

ANATOMY

DESCRIPTIVE AND APPLIED

BY

HENRY GRAY, F.R.S., F.R.C.S.

FORMERLY LECTURER IN ANATOMY AT ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.

TWENTIETH EDITION

EDITED BY

ROBERT HOWDEN

M.A., D.Sc., M.B., C.M.

PROFESSOR OF ANATOMY IN THE UNIVERSITY OF DURHAM

NOTES ON APPLIED ANATOMY

REVISED BY

A. J. JEX-BLAKE, M.A., M.D.Oxon., F.R.C.P.Lond.

SENIOR ASSISTANT PHYSICIAN TO ST. GEORGE'S HOSPITAL

AND

W. FEDDE FEDDEN, M.B., M.S.Lond., F.R.C.S.

PROFESSOR AND LECTURER ON SURGERY, ST. GEORGE'S HOSPITAL

*WITH 1168 ILLUSTRATIONS
OF WHICH 520 ARE COLOURED*

LONGMANS, GREEN AND CO.

THE FIRST EDITION OF THIS WORK

WAS DEDICATED TO

SIR BENJAMIN COLLINS BRODIE, BART.

F.R.S., D.C.L.

IN ADMIRATION OF HIS GREAT TALENTS AND IN REMEMBRANCE
OF MANY ACTS OF KINDNESS SHOWN TO THE ORIGINAL
AUTHOR OF THE BOOK FROM AN EARLY PERIOD
OF HIS PROFESSIONAL CAREER

PREFACE

TO

THE TWENTIETH EDITION

THE call for a new edition in a little over eighteen months is proof of the increasing usefulness and popularity of Gray's *Anatomy*.

In this edition, as in the eighteenth and nineteenth, the new or 'Basle' terminology (or an English translation of it) is used, and where a new name differs materially from an old one, the latter is placed within brackets after the former. Both sets of names are indexed.

I tender my best thanks to Dr. J. Acworth Menzies, Professor of Physiology, and to Dr. E. Philip Stibbe, Demonstrator of Anatomy, in this University. Professor Menzies has kindly corrected the histological part of the book, while Dr. Stibbe has helped to revise the text and pass the volume through the press.

The drawings for the new illustrations (about sixty in number) were made by that skilled and painstaking artist, Mr. Sydney A. Sewell.

ROBERT HOWDEN.

UNIVERSITY OF DURHAM COLLEGE OF MEDICINE,
NEWCASTLE-UPON-TYNE, *February*, 1918.

HENRY GRAY, F.R.S., F.R.C.S.

THE readers of Gray's *Anatomy*, the first edition of which was published sixty years ago, may be interested to learn something of its author, Henry Gray. The following information regarding his career has been extracted from an article which appeared in the *St. George's Hospital Gazette* of May 21st, 1908.

Gray, whose father was private messenger to George IV. and also to William IV., was born in 1827, but of his childhood and early education nothing is known.

On the 6th of May, 1845, he entered as a perpetual student at St. George's Hospital, London, and he is described by those who knew him as "a most painstaking and methodical worker, and one who learnt his anatomy by the slow but invaluable method of making dissections for himself."

While still a student he secured, in 1848, the triennial prize of the Royal College of Surgeons for an essay entitled, "The origin, connexions and distribution of the nerves to the human eye and its appendages, illustrated by comparative dissections of the eye in other vertebrate animals."

At the early age of twenty-five he was, in 1852, elected a Fellow of the Royal Society, and in the following year he obtained the Astley Cooper prize of three hundred guineas for a dissertation "On the structure and use of the spleen."

He held successively the posts of demonstrator of anatomy, curator of the museum and lecturer on anatomy at St. George's Hospital, and was in 1861 a candidate for the post of assistant-surgeon. Unfortunately he was struck down by an attack of confluent smallpox, which he contracted while looking after a nephew who was suffering from that disease, and died at the early age of thirty-four. A career of great promise was thus untimely cut short. Writing on June 15th, 1861, Sir Benjamin Brodie said, "His death, just as he was on the point of obtaining the reward of his labours . . . is a great loss to the Hospital and School."

In 1858 Gray published the first edition of his *Anatomy* which covered 750 pages and contained 363 figures. He had the good fortune to secure the help of his friend, Dr. H. Vandyke Carter, a skilled draughtsman and formerly a demonstrator of anatomy at St. George's Hospital. Carter made the drawings from which the engravings were executed, and the success of the book was, in the first instance, undoubtedly due in no small measure to the excellence of its illustrations. A second edition was prepared by Gray and published in 1860.

The portrait here given of Gray is a reproduction of one which appeared in the *St. George's Hospital Gazette* of May 21st, 1908, where the original is described as being "a very faded photograph taken by Mr. Henry Pollock, second son of the late Lord Chief Baron, Sir Frederick Pollock, and one of the earliest members of the photographic society of London".

Henry Gray

HUMAN ANATOMY

INTRODUCTION

THE term *human anatomy* comprises a consideration of the various structures which make up the human organism. In a restricted sense it deals merely with the parts which form the fully developed individual and which can be rendered evident to the naked eye by various methods of dissection. Regarded from such a standpoint it may be studied by two methods: (1) the various structures may be separately considered—*systematic anatomy*; or (2) the organs and tissues may be studied in relation to one another—*topographical or regional anatomy*.

It is, however, of much advantage to add to the facts ascertained by naked-eye dissection those obtained by the use of the microscope. This introduces two fields of investigation, viz. the study of the minute structure of the various component parts of the body—*histology*; and the study of the human organism in its immature condition, i.e. the various stages of its intra-uterine development from the fertilised ovum up to the period when it assumes an independent existence—*embryology*. Owing to the difficulty of obtaining material illustrating all the stages of this early development, gaps must be filled up by observations on the development of lower forms—*comparative embryology*, or by a consideration of adult forms in the line of human ancestry—*comparative anatomy*. The direct application of the facts of human anatomy to the various pathological conditions which may occur constitutes the subject of *applied anatomy*. Finally, the identification of structures on or immediately underlying the surface of the body is frequently made the subject of special study—*surface anatomy*.

SYSTEMATIC ANATOMY.—The various systems of which the human body is composed are grouped under the following headings:

1. *Osteology*—the bony system or skeleton.
2. *Syndesmology*—the articulations or joints.
3. *Myology*—the muscles. With the description of the muscles it is convenient to include that of the fasciæ which are so intimately connected with them.
4. *Angiology*—the vascular system, comprising the heart, blood-vessels, lymphatic vessels and lymph glands.
5. *Neurology*—the nervous system. The organs of the senses may be included in this system.
6. *Splanchnology*—the visceral system. Topographically the viscera form two groups, viz. the thoracic viscera and the abdominopelvic viscera. The heart, a thoracic viscus, is best considered with the vascular system. The rest of the viscera may be grouped according to their functions: (a) the *respiratory apparatus*; (b) the *digestive apparatus*; and (c) the *urogenital*

apparatus. Strictly speaking, the third sub-group should include only such components of the urogenital apparatus as are included within the abdomino-pelvic cavity, but it is convenient to study under this heading certain parts which lie in relation to the surface of the body, e.g. the testes and the external organs of generation.

For descriptive purposes the body is supposed to be in the erect posture, with the arms hanging by the sides and the palms of the hands directed forwards. The *median plane* is a vertical anteroposterior plane, passing through the centre of the trunk. This plane will pass approximately through the sagittal suture of the skull, and hence any plane parallel to it is termed a *sagittal plane*. A vertical plane at right angles to the median plane passes, roughly speaking, through the central part of the coronal suture or through a line parallel to it; such a plane is therefore known as a *coronal plane*. A plane at right angles to both the median and frontal planes is termed a *transverse* or *horizontal plane*.

The terms *anterior* or *ventral*, and *posterior* or *dorsal*, are employed to indicate the relation of parts to the front or back of the body or limbs, and the terms *superior* or *cephalic*, and *inferior* or *caudal*, to indicate the relative levels of different structures; structures nearer to or farther from the median plane are referred to as *medial* or *lateral* respectively.

The terms *superficial* and *deep* are strictly confined to descriptions of the relative depth from the surface of the various structures: *external* and *internal* are reserved almost entirely for describing the walls of cavities or of hollow viscera. In the case of the limbs the words *proximal* and *distal* refer to the relative distance from the attached end of the limb.

HISTOLOGY

THE ANIMAL CELL

ALL the tissues and organs of the body originate from the fertilised ovum, a microscopic structure consisting of a jelly-like material enclosed in a membrane, and containing a small, spherical, more solid body in its interior; the contained body is called a nucleus, and within it are found one or two distinct spots, termed nucleoli. The fertilised ovum divides and subdivides into an enormous number of similar structures, which are known as cells, and these become variously modified according to the function which they have to perform. Although the cells of the different tissues and organs vary considerably in shape, size, and other characteristics, each consists of a semi-fluid material, known as *protoplasm*, and contains a nucleus. A cell may therefore be defined as a minute nucleated mass of protoplasm (fig. 1).

FIG. 1.—Diagram of a cell.

Protoplasm varies in composition, but in all cases it yields, on analysis, nitrogenous substances, known as proteins. When examined with high powers of the microscope it may appear homogeneous, but many cells show some degree of differentiation into fibrils or granules. After fixation with reagents, such as mercuric chloride, most cells exhibit a reticular, or rather a sponge-like structure, which has a greater affinity for dyes than the material contained in its meshes. It was formerly believed that living protoplasm had a similar structure, and consisted of a fibrillar network, or *spongioplasm*, with a more fluid material, or *hyaloplasm*, in its interstices. The view most commonly held at the present time, however, is that the large molecules of which protoplasm is composed are so arranged as to form two distinct 'phases.' The result is a structure resembling foam, and consisting of minute spaces containing fluid material and bounded by a less fluid phase

formed by a closer aggregation of the molecules. Whether this view be correct or not, it is convenient in the meantime to retain the terms spongioplasm and hyaloplasm to indicate the structure seen in the fixed and stained cell.

The protoplasm of cells frequently contains granules of foreign material, such as glycogen, fat, or pigment. These may have been either formed in the cell or taken in from without, and are spoken of as *paraplast* or *deuterooplasm*.

Few animal cells resemble the ovum in possessing a definite cell-membrane: in those which do not, the surface exhibits certain physical properties which point to a local condensation of some of the protoplasmic constituents. According to Overton these are of a fatty nature and are known as lipoids.

The **nucleus**, in fixed and stained preparations, exhibits a differentiation into a network, or *karyomitome*, and a more fluid material, or *karyoplasm*, in the meshes of the network. The karyomitome is condensed at the periphery of the nucleus to form a well-defined wall, the *nuclear membrane*, and consists of particles of a substance, called *chromatin* because of its affinity for basic dyes, imbedded in a homogeneous material, *linin*, which stains with acid dyes. The staining properties of chromatin are due to the presence of nucleic acid.

The **nucleolus** is a small, spherical, highly refracting body, which stains with acid dyes. Nodes of the chromatin network are liable to be mistaken for nucleoli, but may be distinguished by their irregular shape and staining affinities; they are known as *pseudonucleoli*.

A **centrosome** is present in most cells. It lies near the nucleus, and consists of a small, spherical area of clear protoplasm, in the middle of which is a minute spot or *centriole*. The centrosome is often called the *attraction sphere* because rows of granules in the protoplasm immediately surrounding it are arranged so that they radiate outwards from it like the rays of the conventional sun.

Reproduction of cells is effected either by *direct* or by *indirect division*. In reproduction by *direct division* the nucleus becomes constricted in its centre, assuming an hour-glass shape, and then divides into two. This is followed by a cleavage or division of the whole protoplasmic mass of the cell; and thus two daughter cells are formed, each containing a nucleus. The daughter cells are at first smaller than the original mother cell; but they grow, and the process may be repeated in them, so that multiplication may take place rapidly. Direct division is said to occur in the epithelial cells lining the bladder. *Indirect division* or *karyokinesis* (*karyomitosis*) has been observed in generative cells, epithelial cells, connective tissue-cells, muscular tissue, and nerve-cells. It is possible that cell-division may always take place by the indirect method, and that in those cases in which direct division has been described the intermediate stages may not have been seen; owing to the process occurring more rapidly than usual.

The process of indirect cell-division is characterised by a series of complex changes in the nucleus, leading to its subdivision; this is followed by cleavage of the cell protoplasm. Starting with the nucleus in the quiescent or *resting* stage, these changes may be briefly grouped under the three following phases (fig. 2):

1. **Anaphase**.—The nuclear network of chromatin filaments assumes the form of a twisted *skein* or *spirem*, while the nuclear membrane and nucleolus disappear. The convoluted skein of chromatin divides into a definite number of V-shaped segments or *chromosomes*. The number of chromosomes varies in different animals, but is constant for all the cells in an animal of any given species; in man the number is given by Flemming and Duesberg as twenty-four.* Coincidentally with or preceding these changes, the centrosome, which usually lies by the side of the nucleus, undergoes subdivision, and the two resulting centrosomes are seen to be connected by a spindle of delicate achromatic fibres, the *achromatic spindle*. The centrosomes move away from each other—one towards either extremity of the nucleus—and the fibrils of the achromatic spindle are correspondingly lengthened. A line encircling the spindle midway between its extremities or *poles* is named the *equator*, and around this the V-shaped chromosomes arrange themselves in the form of a star, thus constituting the *monaster*.

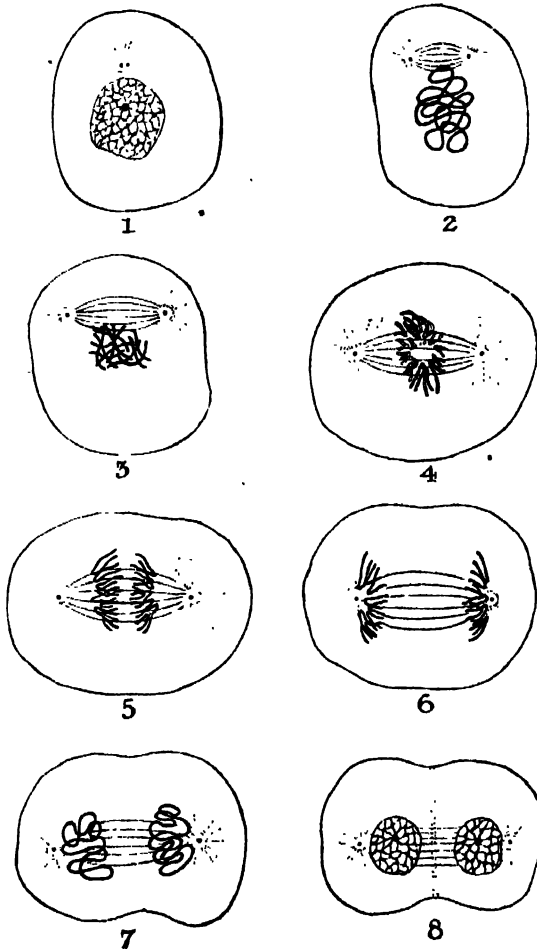

2. **Metaphase**.—Each V-shaped chromosome undergoes longitudinal cleavage into two equal parts or *daughter chromosomes*, the cleavage commencing at the apex of the V and extending along its divergent limbs. The daughter chromosomes, thus separated, travel in opposite directions along the fibrils of the achromatic spindle towards the centrosomes, around which they group themselves, and thus

* Dr. J. Duesberg, *Anat. Anz.*, Band xxviii, S. 475.

two star-like figures are formed, one at either pole of the achromatic spindle. This constitutes the *diaster*.

3. *Kataphase*.—The daughter chromosomes arrange themselves into a *skein* or *spirem*, and eventually form the network of chromatin which is characteristic of the resting nucleus. The nuclear membrane and nucleolus are also differentiated during this phase. The cell-protoplasm begins to appear constricted around the equator of the achromatic spindle, where double rows of granules are also sometimes seen. The constriction deepens and the original cell is gradually divided.

FIG. 2.—Diagram showing the changes which occur in the centrosome and nucleus of a cell in the process of mitotic division, as seen in the epidermis of a larval salamander.

1 to 4 Anaphase ; 5 and 6, Metaphase ; 7 and 8, Kataphase.

The term *telophase* is sometimes applied to the concluding steps of the process of division, in which the daughter cells are finally separated and their nuclei and centrosomes assume the characteristics of the resting stage.

Heterotypical and homotypical mitosis.—In the case of the cells of the reproductive glands the mitotic process differs from that described above. After the formation of the chromosomes, pairs of these structures become connected by their ends so as to form elongated rings. The centrosomes of the daughter nuclei are formed by the breaking of these rings across the middle. Each chromosome then splits in its length into two. No kataphase occurs, and division of the original cell takes place. This process is known as *heterotypical mitosis*, and it is immediately

HISTOLOGY

followed by a division of each daughter cell, known as *homotypical mitosis*, in which the chromosomes separate into two equal groups, one group for each new cell. Each nucleus resulting from homotypical mitosis has thus one-half of the number of chromosomes normal for the species, and it passes through a kataphase to form a typical resting nucleus.

EPITHELIUM

All the surfaces of the body—the external surface of the skin, the internal surfaces of the digestive, respiratory, and genito-urinary tracts, the closed serous cavities, the inner coats of the vessels, the acini and ducts of all secreting and ex-

FIG. 3.—Simple pavement epithelium.

creting glands, the ventricles of the brain and the central canal of the medulla spinalis—are covered by one or more layers of cells, called *epithelium* or *epithelial cells*. These cells are also present in the terminal parts of the organs of special sense, and in some other structures, such as the hypophysis cerebri and the thyroid gland. They serve various purposes. Thus, in the skin, the main purpose served by the epithelium (here called the *epidermis*) is that of protection; as the surface is worn away by the agency of friction new cells

are supplied, and thus the true skin and the vessels and nerves which it contains are defended from damage. The epithelial cells of the salivary glands, the pancreas, the gastric glands, and the glands of the small intestine prepare the digestive juices; those covering the intestinal villi are concerned with the absorption of the products of digestion; similar cells lining the kidney tubules excrete waste products; others, such as those lining the serous cavities, provide a smooth, moist surface.

Epithelium consists of one or more layers of cells, usually supported on a basement membrane, and united together by cement substance, which is similar in chemical composition to the matrix or ground substance of the connective tissues, and has the property of reducing nitrate of silver. Epithelium is naturally grouped into two classes according to whether there is a single layer of cells (*simple epithelium*), or more than one (*stratified epithelium* and *transitional epithelium*).

Simple epithelium.—The different varieties of simple epithelium are squamous or pavement, columnar, glandular, and ciliated.

Simple squamous or *pavement epithelium* (fig. 3) is composed of flat, nucleated cells of different shapes, usually polygonal, and varying in size. These cells fit together by their edges, like the tiles of a mosaic pavement. The nucleus is generally flattened, but may be spheroidal. The protoplasm of the cell may be fibrillated, the fibrils of adjacent cells being continuous across the intervening cement. This kind of epithelium forms the lining of the alveoli of the lungs. The so-called *endothelium*, which covers the serous membranes, and which lines the heart, blood-vessels and lymphatics, is also of the pavement type.

Columnar or *cylindrical epithelium* (fig. 4) consists of cylindrical or rod-shaped cells set together so as to form a complete layer, resembling, when viewed in profile, a palisade. The cells have a prismatic figure, from mutual pressure, and are set upright on the surface which supports them. The cell-protoplasm is always more or less reticulated; the nucleus is oval in shape and contains an intranuclear network;

FIG. 4.—Columnar epithelial cells from the small intestine of the cat. $\times 600$.

a, side view; b, cells seen from surface.

the centriole is double and lies near the surface of the cell. In the columnar epithelium of the intestinal villi, the free border of each cell shows a refractive cap which exhibits well-defined vertical striations. Columnar epithelium lines nearly the whole gastro-intestinal tract and its glands, the greater part of the male urethra, the ductus deferens, the tubules and ducts of the prostate, the bulbo-urethral glands of Cowper, and the vestibular glands of Bartholin. In a modified form it also covers the ovary.

Goblet- or chalice-cells are modified columnar cells. Each appears to be formed by an alteration in shape of a columnar cell (ciliated or otherwise) consequent on the formation of granules, which consist of a substance called *mucigen*, in the interior of the cell. This distends the upper part of the cell, while the nucleus is pressed down towards its deep part, until the cell bursts and the mucus is discharged on to the surface of the mucous membrane (fig. 5), the cell then assuming the shape of an open cup or chalice. A double centriole is found in the mucin-containing part of the goblet cell. Cells of this kind are especially numerous in the mucous membrane of the stomach, and in the glands of the large intestine; they also occur in the epithelial covering of the villi of the small intestine and in that lining the respiratory tract (fig. 7).

Glandular epithelium (fig. 6) is composed of polyhedral, columnar or cubical

FIG. 5.—Goblet cells of a frog
× 500.

FIG. 6.—Isolated liver cells of a rabbit. × 500.

FIG. 7.—Ciliated epithelium from the trachea of a kitten. × 255.

cells. The protoplasm shows a fine reticulum, which gives to the cells a granular appearance. Besides these protoplasmic 'granules,' gland cells usually contain true granules which are the products of their own activity. These are in many cases zymogenic in nature, that is, they are, or contain, the precursors of enzymes or ferments.

Ciliated epithelium (fig. 7) is generally columnar in shape. It is distinguished by the presence of minute processes, like hairs or eyelashes (cilia), standing up from the free surface. The cilia (fig. 8), at their points of attachment to the free border of the cell, possess small nodular enlargements (*basal knobs* of Engelmann); from these knobs fine beaded filaments extend through the cell, and converge to a point near the fixed extremity. The basal knobs or particles have been supposed to be formed by division of the centriole. If the cells be examined during life or immediately on removal from the living body (for which in the human subject the removal of a nasal polypus offers a convenient opportunity) in a weak solution of salt, the cilia will be seen in lashing motion; and if the cells be separated, they will often be seen to be moved about in the field by this ciliary action.

FIG. 8.—Isolated ciliated cell (semidiagrammatic).

Ciliated epithelium lines the respiratory tract from the nose downwards to the smallest ramifications of the bronchial tubes (except in the lower part of the pharynx and on the surfaces of the vocal folds); the tympanic cavity and auditory tube; the uterine tube and the cavity of the body of the uterus; the vasa efferentia; coni vasculosi and the first part of the ductus deferens; the ventricles of the brain and the central canal of the medulla spinalis.

FIG. 9.—Stratified epithelium from the œsophagus.

FIG. 10.—Epithelial cells from the oral cavity of man. $\times 350$.

a. Superficial. b. From deeper layers. c. Cell with two nuclei.

Stratified epithelium (fig. 9) consists of several layers of cells. The cells vary greatly in shape; those of the deepest layer are for the most part columnar, and are placed vertically on the basement membrane; above these are several layers of polyhedral cells, which as they approach the surface become more and more compressed, until the superficial ones are found to consist of flattened scales (fig. 10),

FIG. 11.—Portion of epidermis from a section of the skin of the sole of the foot. $\times 250$.

which overlap one another so as to present an imbricated appearance. The epithelium of the skin, or epidermis, is peculiar in that it shows four distinct layers. The deep layer consists of columnar and polyhedral cells as in stratified squamous epithelium generally (stratum mucosum). In the next layer, or stratum granulosum, the cells are fusiform in section, and contain granules of a substance called *eleidin*. The third layer, or stratum lucidum, consists of cells in which the eleidin has undergone a transformation into a substance called *keratohyalin*; and the cells of the

most superficial layer (stratum corneum) are completely converted into a horny material, known as *keratin* (fig. 11).

The cells of the deeper layers of stratified squamous epithelium are called *prickle-cells*; they are not closely joined together by cement-substance, but are separated from each other by intercellular channels, between which are protoplasmic bridges containing fine fibrils which connect the adjacent cells with each other. When a cell is isolated, it appears to be covered over with a number of short spines, in consequence of the bridges being broken through.

Stratified epithelium is found in the skin, in the conjunctiva, on the anterior surface of the cornea, and in the mucous membrane of the mouth, lower part of the pharynx, œsophagus, vagina and part of the cervix uteri.

Transitional epithelium occurs in the ureters and urinary bladder. Here the cells of the most superficial layer are large and flattened, with depressions on their under surfaces to fit on to the rounded ends of the cells of the second layer, which are pear-shaped, the apices touching the basement membrane. Between the tapering points of the cells of the second layer is a third variety of cells of smaller size than those of the other two layers (fig. 12). In the distended condition of the bladder the superficial cells are more flattened, and the pear-shaped cells are shorter and broader than they are when the bladder is contracted.

FIG. 12.—Transitional epithelium.

CONNECTIVE TISSUES

The term **connective tissue** includes a number of tissues which have a passive function, that of binding together or supporting the functionally active structures; they differ considerably from each other in appearance, but present many points of relationship, and are, moreover, developed from the same layer of the embryo, the mesoderm. They are divided into three great groups: (1) the connective tissues proper, (2) cartilage, and (3) bone.

The circulating fluids (although functionally and probably developmentally different) are regarded by some histologists as a form of connective tissue, and are dealt with in this section.

THE CONNECTIVE TISSUES PROPER

Several varieties of connective tissue are recognised: (1) Areolar tissue. (2) White fibrous tissue. (3) Yellow elastic tissue. (4) Mucous tissue. (5) Retiform tissue. They are all composed of a homogeneous matrix, in which are imbedded cells and fibres—the latter of two kinds, white, and yellow or elastic. The distinction between the different varieties depends upon the relative preponderance of one or other kind of fibre, of cells, or of matrix.

Areolar tissue (fig. 13) is so called because, when artificially distended with air or fluid, it exhibits intercommunicating areolæ or spaces. It is extensively distributed and its chief use is to bind parts together, though allowing, in virtue of its extensibility and elasticity, a considerable amount of movement to take place. It occurs as subcutaneous tissue, as the submucous coat in the digestive tract and elsewhere, and as subserous tissue. It is also found between muscles, vessels, and nerves, forming investing sheaths for them, and connecting them with surrounding structures. It is present in the interior of organs, binding together the lobes and lobules of the compound glands, the various coats of the hollow viscera, and the fibres of muscles and nerves.

When areolar tissue is stretched it is seen to be made up of soft elastic threads, resembling spun silk, and interlacing in all directions. A thin layer, examined under the microscope, shows fibres and cells, imbedded in a homogeneous ground substance or *matrix*.

The fibres form an irregular meshwork, and are of two kinds, white and yellow. The *white fibres* are exceedingly fine; they are colourless, homogeneous and

HISTOLOGY

transparent, and are arranged parallel to each other in bundles, which have a wavy course. The individual fibres do not branch, but small bundles of them may leave one

FIG. 13—Subcutaneous tissue from a young rabbit. Highly magnified. (From .. Schäfer's Essentials of Histology.)

c, c'. Lamellar cell. f. Fibrillated cell. g. Plasma-cell. p. Clasmatocytes.

large bundle to join another. The *yellow* or *elastic* fibres have well-defined outlines, and are usually somewhat larger than the white fibres, varying in diameter from

FIG. 14—Areolar tissue of a rabbit, silvered. $\times 255$.
Ground substance stained, cells unstained.

1μ to 6μ .* They are pale yellow in colour, homogeneous in appearance, run a comparatively straight course, branch, and anastomose freely with each other.

* A micromillimetre (μ) is $\frac{1}{1000}$ of a millimetre or $\frac{1}{25400}$ of an inch.

When they are broken across, the ends tend to curl up. They also differ from the white fibres in staining a dark red colour with orcein.

The cells of areolar tissue are of four principal kinds: (1) Flattened *lamellar cells*, may be either branched or unbranched. The branched lamellar cells are composed of clear protoplasm, with few granules, and contain oval nuclei; their processes may unite with those of neighbouring cells, so as to form a syncytium, as in the cornea. Occasionally a cell may be found which shows fibrillation of its protoplasm. Some observers believe such a condition to be a stage in the formation of the white fibres. The unbranched cells are joined edge to edge like the cells of an epithelium; the flattened cells lining the serous cavities are examples of this variety. (2) *Clasmatocytes* are large irregular cells characterised by the presence of granules or vacuoles in their protoplasm, and containing oval nuclei. (3) *Granule-cells* are ovoid or spheroidal in shape and contain basiphil granules. (4) *Plasma-cells* of Waldeyer are usually spheroidal in shape and distinguished by containing a vacuolated protoplasm; the vacuoles are filled with fluid, and the protoplasm between them is clear, with occasionally a few scattered basiphil granules.

In addition to these four types of cells, areolar tissue may contain *wandering cells*, i.e. leucocytes which have emigrated from the neighbouring vessels; in some instances, as in the choroid coat of the eye, cells filled with granules of pigment (*pigment-cells*) are found.

The cells lie in spaces in the ground substance between the bundles of fibres, and these spaces may be brought into view by treating the tissue with nitrate of silver and exposing it to the light; this will colour the ground substance and leave the cell-spaces unstained (fig. 14).

Adipose tissue.—In almost all parts of the body areolar tissue contains a variable quantity of adipose tissue or fat. The principal situations where it is not found are the subcutaneous tissue of the eyelids, of the penis and scrotum, of the labia minora; within the cavity of the cranium; and in the lungs, except near their

FIG. 15.—Adipose tissue. Highly magnified.

α . Starlike appearance, from crystallisation of fatty acids.

roots. The distribution of adipose tissue is not uniform; in some parts it is in great abundance, as in the subcutaneous tissue, especially of the abdomen, around the kidneys, and in the mesentery and omentum. Lastly, fat enters largely into the formation of the marrow of bones.

Adipose tissue consists of *fat-cells*, lodged in the meshes of areolar tissue. Fat-cells (fig. 15) vary in size, the average diameter being about 50μ ; each consists of an exceedingly delicate protoplasmic membrane, filled with fatty matter, which is liquid during life, but solidifies after death. They are round or spherical where they are not subjected to pressure; otherwise they are more or less polygonal. A nucleus is always present under the cell-membrane and can be demonstrated by staining with hæmatoxylin; in the natural condition it is so compressed by the

contained oily matter as to be scarcely recognisable. The fat-cells are held together mainly by the network of capillary blood-vessels which is distributed to them.

FIG. 16.—Development of fat.
(Klein and Noble Smith.)

a. Minute artery. r. Minute vein. c. Capillary blood-vessels in the course of formation; they are not yet completely hollowed out, there being still left in them protoplasmic septa. d. The ground-substance, containing numerous nucleated cells, some of which are more distinctly branched and flattened than others, and appear therefore more spindle-shaped.

Chemically the oily material is composed of olein, palmitin, and stearin, which are glycerol esters of fatty acids. Sometimes fat-crystals form in the cells after death (fig. 15. a). By boiling the tissue in ether or strong alcohol, the fat may be extracted from the cells, leaving them empty and shrunken.

Fat first appears in the human embryo about the fourteenth week. The fat-cells are formed by the transformation of connective tissue cells. Small droplets of oil are formed in the protoplasm, and these coalesce to produce a larger drop, which increases until it distends the cell, the remaining protoplasm and the nucleus being displaced towards the periphery (fig. 16).

White fibrous tissue is a true connecting structure, and serves three purposes in the animal economy. In the form of ligaments it binds bones together; in the form of tendons it connects muscles with bones or other structures; it constitutes investing or protecting membranes to various organs. Examples of such membranes are to be found in the muscular fasciæ or sheaths, the periosteum, and the perichondrium; the capsules of the various glands; the investing sheaths of the nerves (perineurium), and of various organs, as the penis and the eye.

In white fibrous tissue, as its name implies, the white fibres (fig. 17) predominate: the matrix is apparent only as a cement-substance, yellow elastic fibres

FIG. 17.—White fibres. $\times 350$.

FIG. 18.—Tendon of a rat's tail, stained with gold chloride, showing chains of cells between the tendon-bundles. $\times 250$.

are comparatively few, while the tissue-cells are arranged in a special manner. It presents to the naked eye a silvery white glistening appearance; it is devoid of elasticity, and has only the very slightest extensibility; it is exceedingly strong, so that upon the application of any external violence, a bone with which it is connected may fracture before the fibrous tissue gives way. In ligaments and tendons the bundles of fibres run parallel with each other; in membranes they intersect

one another. The cells found in white fibrous tissue are often called 'tendon-cells.' They are situated on the surfaces of groups of fibres, and are arranged in rows, each cell being separated from its neighbours by a narrow line of cement-substance. The nucleus is generally situated at one end of the cell, the nucleus of the adjoining cell being in close proximity to it (fig. 18). The tendon-cells have

FIG. 19.—Transverse section of a tendon of a rat. $\times 120$.

wing-like processes which pass between the bundles of fibres, giving a stellate appearance in transverse section (fig. 19). When viewed from the side, the cell with its wings is quadrangular, and there may be the appearance of a vertical line on the body of the cell owing to the projection of a wing towards the eye of the observer (fig. 18). Upon the addition of acetic acid white fibrous tissue swells up into a glassy-looking indistinguishable mass. When boiled in water it is converted almost completely into gelatin, the white fibres being composed of *collagen*, which is regarded as the anhydride of gelatin.

Yellow elastic tissue.—In certain parts of the body a tissue is found which is of a yellowish colour, and possessed of great elasticity. It is capable of considerable

extension, and when the extending force is withdrawn returns at once to its original condition. This is *yellow elastic tissue*; it may be regarded as a connective tissue in which the yellow elastic fibres have developed to the practical exclusion of the other elements. It is found in the ligamenta flava, in the vocal folds and conus elasticus of the larynx, in the mucous membrane of the trachea and bronchi, in the walls of the pulmonary air-vesicles, in the coats of the blood-vessels, especially the

larger arteries, and to a very considerable extent in the hyothyroid and stylohyoid ligaments. It is also found in the ligamentum nuchæ of the lower animals (fig. 20). Where the fibres are broad and large and the network close, the tissue presents the appearance of a membrane, with gaps or perforations corresponding with the intervening spaces. This is found in the inner coat of the arteries, and to it the name of *fenestrated membrane* has been given by Henle. Yellow elastic fibres

FIG. 20.—Ligamentum nuchæ of the ox, stained with picrocarmine. $\times 280$.

a. Longitudinal section. b. Transverse section.

remain unaltered by acetic acid; chemically they are composed of the sclero-protein known as *elastin*.

Mucous tissue exists in the 'jelly of Wharton,' which forms the bulk of the umbilical cord, but is also found in the foetus, chiefly as a stage in the development of connective tissue. It consists of a matrix, largely made up of mucin, in which are nucleated cells with branching and anastomosing processes (fig. 21). Few fibres are seen in typical mucous tissue, though at birth the umbilical cord shows a considerable development of fibres. In the adult the vitreous body of the eye is a persistent form of mucous tissue, in which the fibres and cells are very few in number.

Retiform or reticular tissue (fig. 22) is found extensively in many parts of the body, constituting the framework of some organs and entering into the construction of many mucous membranes. It is a variety of connective tissue, in which the intercellular or ground-substance is, in a great measure, replaced by fluid. It is composed almost entirely of extremely fine bundles of white fibrous tissue,

FIG. 21.—Mucous tissue from the umbilical cord of a human embryo of four months.
× 255. Stained with hæmatoxylin and eosin.

forming an intricate network, and chemically it yields *gelatin* on boiling. The fibres are covered and concealed in places by flattened branched connective tissue cells. In many situations the interstices of the network are filled with rounded lymph-corpuscles, and the tissue is then termed **lymphoid** or **adenoid tissue**.

Basement membranes consist of thin sheets of modified connective tissue, and are found underlying layers of epithelial cells, for example, in mucous membranes and secreting glands. They may be formed of cells or of condensed ground-substance. In the former case, flattened cells, which are modified connective tissue corpuscles, are united by their edges by means of cement-substance, which can be demonstrated by staining with silver nitrate; if the cells are unbranched, the membrane is continuous; if they are branched, the processes are united, and the membrane is fenestrated. The basement membrane underlying the epithelium on the anterior surface of the cornea is composed of ground-substance.

Vessels and nerves of connective tissue.—The *blood-vessels* of connective tissue are very few—that is to say, few are supplied to the tissue itself, although many carrying blood to other structures may permeate one of its forms, the areolar tissue. In white fibrous tissue the blood-vessels usually run parallel to and between the longitudinal bundles, sending communicating branches across the bundles; in some forms, as in the periosteum and dura mater, they are fairly numerous. In yellow elastic tissue, the blood-vessels also run between the fibres. *Lymphatic*

vessels are very numerous in most forms of connective tissue, especially in the areolar tissue beneath the skin and the mucous and serous surfaces. They are also found in abundance in the sheaths of tendons, as well as in the tendons themselves.

FIG. 22.—Retiform and adenoid tissue, from a lymph gland. $\times 255$.

Nerves are found in white fibrous tissue, where they end in a special manner; but it is doubtful whether any nerves end in areolar tissue; at all events, they have not yet been demonstrated, and the tissue is possessed of very little sensibility.

Pigment.—Pigment is found in various parts of the body; most frequently in epithelial cells and in the cells of connective tissue. Pigmented *epithelial cells* are present in the external layer of the retina, on the posterior surface of the iris, in the olfactory region of the nose, in the membranous labyrinth of the ear, in the deeper layers of the cuticle, and in the hairs. Pigment is abundantly present in the skin of the coloured races, but in the skin of white races it is well marked only in the areolæ round the mammary papillæ and in irregular coloured patches. Pigmented *connective tissue cells* are frequently met with in the lower vertebrates. In man they are found in the chorioid coat of the eye (fig. 23), and in the iris of all but the light blue eyes and the albino. The cells are usually large and branched, and are filled with brown or black granules, consisting of *melanin*. In the retina the processes of the cells extend between the rods and cones; when the eye is exposed to light the pigment-granules extend into these processes, and under the influence of darkness they are withdrawn into the body of the cell.

FIG. 23.—Pigment-cells from the chorioid coat of the eyeball.

The pigment-granules are of very small size and are closely packed within the cells, but do not invade the nuclei. Occasionally they are yellow, and when occurring in the cells of the cuticle constitute 'freckles.' In the retina another variety of pigment occurs, known as *rhodopsin* or *visual purple*, which is bleached on exposure to light.

Applied Anatomy.—Abnormal pigmentation of the skin may be congenital, when it often takes the form of dark brown or black *nævi* (moles), scattered over a greater or smaller area of the body. It may also result from the prolonged consumption of various drugs, particularly of salts of silver or arsenic, being most marked wherever the skin is exposed to the action of light. Progressive darkening or bronzing of the skin is also highly suggestive of Addison's disease, which commonly follows destruction or tuberculosis of the suprarenal glands; it is then most obvious in regions where the skin is normally pigmented or is subjected to pressure or irritation from the clothes. Pigmentation is also associated with certain disorders of the skin, of the female genitalia, and of the thyroid gland, and with the later stages of wasting diseases such as cancer and phthisis. It does not yield to any medical treatment as a rule.

• **Development of connective tissue.**—Connective tissue is developed from cells of the mesoderm. These cells multiply and form a syncytium containing many nuclei. The ground-substance appears in spaces between the cells as an albuminous fluid. Later, granules are deposited in the ground-substance by the activity of the cells, and become fused to form the fibres of the tissue.

CARTILAGE

Cartilage is a non-vascular structure found in various parts of the body—in the joints, parietes of the thorax, trachea, bronchi, nose, and ears. In the foetus.

FIG. 24.—Cartilage cells in the costal cartilage of a kitten. $\times 250$.

Cartilage-cell containing fat

at an early period, the greater part of the skeleton is cartilaginous; as this cartilage is afterwards replaced by bone, it is called *temporary*, in contradistinction to that which remains unossified during the whole of life and is called *permanent*.

Cartilage is divided, according to its minute structure, into *hyaline cartilage*, *white fibrocartilage*, and *yellow* or *elastic fibrocartilage*. Besides these varieties met with in the adult human subject, there is a variety called *cellular cartilage*, formed entirely, or almost entirely, of cells, separated from each other by their capsules only, which in this kind of cartilage are extremely well marked. Cellular cartilage is found in the external ears of rats, mice, and some other animals, and it also forms a stage in the development of cartilage in human embryonic life.

Hyaline cartilage has a pearly bluish colour and consists of a gristly mass of a firm consistence, but of considerable elasticity. Except where it coats the articular

ends of bones, it is covered by a fibrous membrane, the *perichondrium*, from the vessels of which it imbibes its nutritive fluids, being itself destitute of blood-vessels. It contains no nerves. If a thin slice be examined under the microscope, it will be found to consist of cells of a rounded or bluntly angular form, lying in spaces in a granular or almost homogeneous matrix (fig. 24). The cells are frequently arranged in groups of two or more, and, when this is the case, they have generally straight outlines where they are in contact with each other, but are rounded in the rest of their circumference. They consist of clear translucent protoplasm in which fine interlacing filaments and minute granules are sometimes present; imbedded in the protoplasm are one or two round nuclei, having the usual intranuclear network.

The matrix is transparent and apparently without structure, or else presents a dimly granular appearance, like ground glass. The portion immediately surrounding each cell-space is often well defined, and is further characterised by its affinity for basic dyes. It is known as the *capsule* of the space. The matrix of hyaline cartilage, and especially that of the articular variety, can be broken up into fine fibrils after prolonged maceration. These fibrils are probably of the same nature, chemically, as the white fibres of connective tissue. It is believed by some histologists that the matrix is permeated by a number of fine channels, which connect the cell-spaces with each other and with the lymphatics of the perichondrium, and that in this way nutrient fluid obtains access to the cartilage-cells.

Articular cartilage, costal cartilage, and temporary cartilage are all of the hyaline variety, but they present differences in the size, shape, and arrangement of their cells.

Articular Cartilage (fig. 25) shows no tendency to ossification; its matrix is finely granular, and its cells are flattened and disposed parallel to the surface in the superficial part of the cartilage, while nearer to the bone they are oval and are arranged in vertical rows. It has a tendency to split in a vertical direction. Its free surface is not covered by perichondrium, but the synovial stratum of the articular capsule can be traced over a small part of its circumference, and here the cartilage-cells are more or less branched and pass insensibly into the branched connective tissue cells of the synovial stratum. It forms a thin layer upon the joint-surfaces of the bones, and its elasticity enables it to break the force of concussions, while its smoothness affords ease and freedom of movement. It varies in thickness according to the shape of the articular surface on which it lies; where this is convex the cartilage is thickest at the centre, the reverse being the case on concave articular surfaces. It appears to derive its nutriment partly from the vessels of the synovial stratum of the joint-capsule and partly from those of the bone upon which it is implanted. The minute vessels of the spongy bone dilate and form arches as they approach the articular lamella, and then return into the substance of the bone.

In **costal cartilage** the cells and nuclei are large, and the matrix, which is usually homogeneous and transparent, has a tendency to fibrous striation, especially in old age (fig. 26). In the thickest parts of the costal cartilages a few large vascular channels may be detected. This appears, at first sight, to be an exception to the statement that cartilage is non-vascular, but is not so really, for the vessels give no branches to the cartilage itself, and the channels may rather be looked upon as involutions of the perichondrium. The xiphoid process of the sternum and the cartilages of the nose, larynx, and trachea (except the epiglottis and corniculate

FIG. 25.—Vertical section of articular cartilage.

cartilages of the larynx, which are composed of elastic fibrocartilage) resemble the costal cartilages in microscopical characteristics. The arytenoid cartilage of the larynx shows a transition from hyaline cartilage at its base to elastic cartilage at the apex.

The hyaline cartilages, especially in adult and advanced life, are prone to calcify—that is to say, their matrix becomes permeated by calcium salts. Calcification

occurs frequently in the costal cartilages, and in the cartilages of the trachea, and may be succeeded by ossification.

FIG. 26.—Costal cartilage from a man seventy-six years of age, showing the development of fibrous structure in the matrix. In several portions of the specimen two or three generations of cells are seen enclosed in a parent cell-wall. Highly magnified.

White fibrocartilage consists of fibrous connective tissue arranged in bundles, with cartilage-cells between the bundles; the cells are roughly ovoid in shape, and are surrounded by concentrically striated areas of cartilage-matrix (fig. 27). The white fibrocartilages admit of arrangement into four groups—interarticular, connecting, circumferential, and stratiform.

1. The *interarticular fibrocartilages* (*menisci*) are flattened fibrocartilaginous plates, of a round, oval, triangular, or sickle-like form, interposed between the articular cartilages of certain joints; the synovial stratum of the articular capsule covers their free surfaces. They are found in the temporomandibular, sternoclavicular, acromioclavicular, wrist- and knee-joints. Their uses are to obliterate the intervals between opposed surfaces in their various motions; to increase the depths of the articular surfaces and give ease to the gliding movements; they also increase the varieties of movement in a joint.

2. The *connecting fibrocartilages* are interposed between the bony surfaces of those joints which admit of only slight mobility, as between the bodies of the vertebrae. They form discs which are closely adherent to the opposed surfaces.

FIG. 27.—White fibrocartilage from an intervertebral fibrocartilage.

Each disc is composed of concentric layers of fibrous tissue, with cartilaginous laminae interposed, the former tissue predominating towards the circumference, the latter towards the centre.

3. The *circumferential fibrocartilages* consist of rims of fibrocartilage, which surround the margins of some of the articular cavities, e.g. the glenoidal labrum of the hip-joint and that of the shoulder-joint; they serve to deepen the articular cavities and to protect their edges.

4. The *stratiform fibrocartilages* form thin coatings to osseous grooves through which the tendons of certain muscles glide.

Small masses of fibrocartilage are also developed in the tendons of some muscles, where they glide over bones, as in the tendons of the *Peronæus longus* and *Tibialis posterior*.

Yellow or elastic fibrocartilage is found in the ears, the corniculate cartilages of the larynx, and the epiglottis. It consists of cartilage-cells and a matrix, the latter being pervaded by a network of yellow elastic fibres, branching and anastomosing in all directions, except immediately around the cells, where there is a variable amount of hyaline substance (fig. 28). The fibres resemble those of yellow elastic tissue, not only in appearance, and in being unaffected by acetic acid, but also in their affinity for orcein; according to Rollett their continuity with the elastic fibres of the neighbouring tissue is demonstrable.

The distinguishing feature of cartilage, chemically, is that it yields on boiling a substance called *chondrin*, a mixture of gelatin with mucinoid substances chief among which is a compound termed *chondromucoid*.

FIG. 28.—Yellow or elastic fibrocartilage from the epiglottis of a cat. 250.

BONE

Structure and physical properties.—Bone is one of the hardest structures of the animal body; it possesses also a certain degree of toughness and elasticity. Its colour, in a fresh state, is pinkish white externally, and deep red within. On examining a section of a bone, it is seen to be composed of two kinds of tissue, one of which is dense in texture, like ivory, and is termed *substantia compacta*; the other consists of slender fibres and lamellæ, which join to form a reticular structure; this is called *substantia spongiosa* or, from its resemblance to lattice work, *cancellous tissue*. The compact substance is always placed on the exterior of the bone, the spongy in the interior. The relative quantities of these vary in different bones and in different parts of the same bone, according as strength or lightness is requisite. Close examination of the compact substance shows it to be extremely porous, so that the difference between it and the spongy substance depends merely upon the relative amount of solid matter and the size and number of spaces in each; in the compact substance the spaces are small and the solid matter abundant, while in the spongy substance the spaces are large and the solid matter small in quantity.

During life, bone is permeated by vessels, and enclosed, except where it is coated with articular cartilage, in a fibrous membrane, the *periosteum*, by means of which many of these vessels reach the bone. If the periosteum be stripped from the surface of the living bone, small bleeding points are seen which mark the entrance of the periosteal vessels; and on section every part of the bone exudes blood from the minute vessels which ramify in it. In the interior of the long bones of the limbs is a cylindrical cavity (*cavum medullare*) filled with *medulla ossium* or *marrow*, and lined by a highly vascular areolar structure, called the *medullary membrane* or *internal periosteum*.

The **periosteum** adheres to the surface of the bones in nearly every part, but not to the cartilage covering their articular surfaces. When strong tendons or

ligaments are attached to a bone, the periosteum is incorporated with them. It consists of two layers closely united together, the outer formed chiefly of white fibrous tissue, containing occasionally a few fat-cells; the inner, of elastic fibres of the finer kind, forming dense membranous networks, which can be again separated into several layers. In young bones the periosteum is thick and very vascular, and is intimately connected at either end of the bone with the epiphysial cartilage, but less closely with the body of the bone, from which it is separated by a layer of soft tissue, containing a number of granular corpuscles or 'osteoblasts,' by which ossification proceeds on the exterior of the young bone. Later in life the periosteum is thinner and less vascular, and the osteoblasts are converted into an epithelioid layer on its deep surface. The periosteum serves as a nidus for the ramification of the vessels previous to their distribution in the bone; hence the liability of bone to exfoliation or necrosis when denuded of this membrane by injury or disease. Fine nerves and lymphatics, which generally accompany the arteries, may also be demonstrated in the periosteum.

The **medulla ossium** or **marrow** not only fills up the cylindrical cavities in the bodies of the long bones, but also occupies the spaces of the cancellous tissue and

FIG. 29.—Transverse section of the compact substance of bone.
Magnified. (Sharpey.)

extends into the larger Haversian canals. It differs in composition in different bones. In the bodies of the long bones the marrow is of a *yellow* colour (*medulla ossium flava*), and consists of a basis of connective tissue supporting numerous blood-vessels and cells, most of which are fat-cells, but some are 'marrow-cells,' such as occur in the red marrow. In the flat and short bones, in the articular ends of the long bones, in the bodies of the vertebræ, in the cranial diploë, and in the sternum and ribs, the marrow is of a *red* colour (*medulla ossium rubra*); it consists of marrow-cells, red and white blood-corpuscles, giant-cells, and a few fat-cells, all supported by a reticulum of connective tissue. In post-natal life the red marrow is the chief seat of formation of the corpuscles of the blood, and it will therefore be described more fully in that connexion (p. 28).

Vessels and nerves of bone.—The *blood-vessels* of bone are very numerous. Those of the compact substance are derived from a close network of vessels in the periosteum. Vessels pass from this network into the minute orifices in the compact substance, and run in the Haversian canals which traverse it. The spongy substance is supplied in a similar way by larger vessels, which perforate the outer compact substance, and are distributed to the cavities of the spongy portion of the bone. In the long bones, numerous apertures may be seen at the ends near the articular surfaces; some of these give passage to arteries; but the greater number transmit veins from the spongy substance. The marrow of a long bone is supplied by an artery which enters the bone at the nutrient foramen (*foramen*

nutricium). The *nutrient* artery, usually accompanied by one or two veins, sends branches upwards and downwards, which ramify in the medullary membrane, and give twigs to the adjoining Haversian canals. The ramifications of this vessel anastomose with the arteries of the spongy and compact substances. In most of the flat, and in many of the short bones there are one or more large apertures for the transmission of nutrient vessels. Veins emerge from the long bones as follows:—(1) one or two accompany the nutrient artery; (2) numerous large and small veins emerge near the articular extremities; (3) many small veins pass out of the compact substance. In the flat cranial bones the veins are large and run in tortuous canals in the diploic tissue, the walls of the canals being formed by thin lamellæ of bone, perforated here and there for the passage of branches from the adjacent diploë. The same condition is found in all spongy substance, the veins being enclosed and supported by osseous material, and having exceedingly thin coats. When a bone is divided, the vessels remain open, and do not contract in the canals in which they are contained. *Lymphatic vessels*, which communicate with those in the periosteum, are found in the Haversian canals. *Nerves* are distributed freely to the periosteum, and accompany the nutrient arteries into the interior of the bone. They are said to be most numerous in the articular extremities of the long bones, in the vertebrae, and in the larger flat bones.

Minute anatomy.—If a thin transverse section of dense bone be examined with a low power of the microscope it will be seen to be mapped out into a number of circular districts, each consisting of a central hole surrounded by a number of concentric rings. These districts are termed *Haversian systems*; the central hole is a *Haversian canal*, and the rings are *lamellæ* of bony tissue arranged concentrically around the central canal. Between these lamellæ are a number of small spaces termed *lacunæ*, which are connected with each other and with the central Haversian canal by many fine radiating channels called *canaliculi*. Filling in the irregular intervals between these circular districts are *interstitial lamellæ*, with their *lacunæ* and *canaliculi*, running in various directions, but more or less curved (fig. 29). Again, other lamellæ, found on the surface of the bone, are arranged parallel to its circumference; they are termed *circumferential* or *primary* lamellæ, to distinguish them from those surrounding the Haversian canals, which are termed *secondary* lamellæ.

In a longitudinal section it will be seen that the Haversian canals run parallel with the long axis of the bone for a short distance and then branch and communicate (fig. 30). They vary considerably in size, but their average diameter is about 0.05 mm. The canals near the medullary cavity are larger than those near the surface of the bone. Each canal usually contains a minute artery and vein, a small quantity of delicate connective tissue, and some nerve-filaments; in the larger ones there are also lymphatic vessels, and cells with branching processes.

The *lamellæ* are thin plates of bony tissue. They may be stripped off as thin films from a piece of bone which has been macerated in dilute mineral acid. If one of these films be examined with a high power of the microscope, it will be found to be composed of fine fibres identical with those of white connective tissue. The matrix between the fibres is impregnated with lime-salts which the acid dissolves. The fibres of one lamella are connected by branches with those of adjacent lamellæ. Moreover, the fibres of one lamella usually form an acute

FIG. 30.—Section parallel to the surface from the body of the femur. $\times 100$.

a. Haversian canals. b. Lacunæ seen from the side. c. Others seen from the surface in lamellæ which are cut horizontally.

angle with those of the contiguous layer; in the Haversian systems, however, the fibres of adjacent lamellæ run at right angles to each other. In many places the various lamellæ are held together by tapering fibres, which run obliquely through them, pinning or bolting them together; these fibres were first described by Sharpey, and were named by him *perforating fibres* (fig. 31).

FIG. 31.—Perforating fibres; human parietal bone, decalcified. (H. Müller.) (From Quain's Elements of Anatomy, vol. ii., pt. i., Microscopic Anatomy.)

a. Perforating fibres in situ; b. Fibres drawn out of their sockets, c. Sockets.

The *lacunæ* are oblong spaces situated between the lamellæ, and each lacuna is occupied during life by a branched *bone-cell* (fig. 32), the processes from which extend into the canaliculi.

The *canaliculi* are minute channels, crossing the lamellæ and connecting the lacunæ of a Haversian system with one another, and with the Haversian canal. The canaliculi at the periphery of a Haversian system do not as a rule communicate

FIG. 32.—Nucleated bone-cells and their processes, contained in the bone-lacunæ and their canaliculi respectively. From a section through the vertebra of an adult mouse. (Klein and Noble Smith.)

with those of neighbouring systems, but form loops and return to their own lacunæ. Thus every part of a Haversian system is supplied with nutrient fluids derived from the vessels in the Haversian canal and distributed through the canaliculi and lacunæ.

The *bone-cells* occupy, but do not fill, the lacunæ. They are flattened nucleated branched cells, homologous with the lamellar cells of connective tissue; their branches pass into the canaliculi.

In thin plates of bone Haversian canals are absent.

Chemical composition. Bone consists of an animal and an earthy part intimately combined together.

The animal part may be obtained by immersing a bone for a considerable time in dilute mineral acid, which will dissolve the mineral matter. The bone retains

its shape, but is now perfectly flexible, so that a long bone (one of the ribs, for example) can easily be tied in a knot. In a transverse section of such a softened bone (fig. 33), the arrangement of the Haversian canals, lamellæ, lacunæ, and canaliculi can be recognised.

The earthy part may be obtained by calcination, which destroys the animal matter. The bone retains its original form, but is white and brittle, has lost about one-third of its original weight, and crumbles under the slightest force. The earthy matter, composed chiefly of calcium phosphate, forms about 66·7 per

cent. of the weight of the bone ; it confers on bone its hardness and rigidity, while the animal matter (*ossein*) determines its resiliency and tenacity.

FIG. 33.—Transverse section of the body of a human fibula, decalcified. $\times 250$.

Ossification.—Some bones, such as those of the roof and sides of the skull, are preceded by membrane, but most bones are preceded by rods or masses of cartilage. Hence two kinds of ossification are described ; the *intramembranous* and the *intracartilaginous*.

Intramembranous ossification.—The membrane which occupies the place of the future bone is of the nature of connective tissue, and ultimately forms the

FIG. 34.—Part of the growing edge of the developing parietal bone of a fetal cat. (After J. Lawrence.)

periosteum ; it is composed of fibres and granular cells in a matrix richly supplied with blood-vessels. The peripheral portion is more fibrous, while in the central portion the cells or *osteoblasts* predominate. At the outset of the process of bone formation a little network of fibres radiates from the centre of ossification. These rays consist at their growing points of a network of fine clear fibres and granular corpuscles with an intervening ground-substance (fig. 34). The fibres are termed

osteogenetic fibres, and differ little from those of white fibrous tissue. The membrane assumes a dark and granular appearance from the deposition of calcareous granules in the matrix between the fibres, and in the calcified material some of the granular cells or osteoblasts are enclosed. By the fusion of the calcareous granules the tissue again assumes a more transparent appearance, but the fibres are no longer so distinctly seen. The osteoblasts form the bone-cells of the future bone, the spaces in which they are enclosed constituting the lacunæ. As this process advances, a network of bone is formed, the meshes of which contain the blood-vessels and a

FIG. 35.—Section of a fetal bone of a cat.

im. Subperiosteal bony deposit. *ir.* Irruption of the subperiosteal tissue. *o.* Layer of osteoblasts. *p.* Fibrous layer of the periosteum.

delicate connective tissue crowded with osteoblasts. The bony trabeculae thicken by the addition of fresh layers formed by the osteoblasts on their surface, and the meshes are correspondingly encroached upon. Subsequently the bone increases in thickness by the deposition of successive layers under the periosteum and round the larger vascular channels which become the Haversian canals.

Intracartilaginous ossification.—

Most of the bones are ossified in cartilage. In a long bone, which may be taken as an example, the process commences in the centre and proceeds towards the extremities, which for some time remain cartilaginous. Subsequently a similar process commences at one or more centres in the extremities, and gradually extends through them. The ossified extremities do not, however, fuse with the body of the bone until growth has ceased; between the body and either extremity a plate of cartilage termed the *epiphysial cartilage* persists for a time.

At the centre of ossification, or point where the ossifying process begins, the cartilage-cells multiply and enlarge and arrange themselves in rows (fig. 35). The matrix in which they are imbedded increases in quantity, so that the cells are further separated from each other.

A deposit of calcareous material now takes place in this matrix, so that it presents a granular and opaque appearance. The cartilage-

cells are enclosed in oblong cavities, the walls of which are formed of calcified matrix which cuts off all nutrition from the cells; the cells, in consequence, atrophy, leaving spaces called the *primary areolæ*.

While this process is going on in the centre of the bar of cartilage, certain changes are taking place on its surface. This is covered by a very vascular membrane, the *perichondrium*, formed of connective tissue similar to that already described as constituting the basis of membrane-bone; on the inner surface of this—that is to say, on the surface in contact with the cartilage—are gathered the formative cells, the *osteoblasts*. By the agency of these cells a thin layer of bony tissue is laid down, between the perichondrium and the cartilage, by the *intramembranous* mode of ossification just described. There are then, in this first stage, two processes going on simultaneously: in the centre of the cartilage the formation of a number of oblong spaces, bounded by calcified matrix and containing the withered cartilage-

cells, and on the surface of the cartilage the formation of a layer of true membrane-bone. The second stage consists in the prolongation into the cartilage of processes of the deeper or osteogenetic layer of the perichondrium (now periosteum) (fig. 35, *iv*). The processes consist of blood-vessels and cells—*osteoblasts*, or bone-formers, and *osteoclasts*, or bone-destroyers. The latter are large, multinucleated protoplasmic masses, and they excavate passages through the new-formed bony layer by absorption, and pass through it into the calcified matrix (fig. 36). Wherever these processes of the osteogenetic layer come in contact with the calcified walls of the primary areolæ they absorb them, and thus cause a fusion of the original cavities and the formation of larger spaces, which are termed the *secondary areolæ* or *medullary spaces*. These secondary spaces are filled with embryonic marrow, consisting of osteoblasts and vessels, derived, in the manner described above, from the osteogenetic layer of the periosteum (fig. 36).

The walls of the secondary areolæ increase in thickness by the deposition of layers of bone on their surface. This process takes place in the following manner. Some of the osteoblasts of the embryonic marrow, after undergoing rapid division, arrange themselves as a layer on the surface of the wall of the space (fig. 36). This layer of osteoblasts forms a bony stratum, which gradually covers the wall of the space and in which some of the osteoblasts are included as bone cells. The next stage in the process consists in the removal of these primary bone spicules by the osteoclasts, one of which may be seen lying in a Howship's foveola at the free end of each spicule (fig. 37). The removal of the primary spicules goes on *pari passu* with the formation of permanent bone by the periosteum, and in this way the medullary cavity of the bone is formed.

This series of changes proceeds gradually towards the ends of the bone, so that all the changes described above may be seen in different parts, from the true bone at the centre of the body to the hyaline cartilage at the extremities.

While the ossification of the cartilaginous body is extending towards the articular ends, the cartilage immediately in advance of the osseous tissue continues to grow until the length of the adult bone is reached.

The articular end remains for some time cartilaginous, and then one or more bony centres, or epiphyses, appear, and initiate in it the process of ossification; but the extremity remains separated from the body of the bone by a narrow cartilaginous layer, the *epiphysial cartilage*, for a definite time. This cartilage ultimately ossifies, and the bone assumes its completed form and shape. The same remark applies to such processes of bone as are ossified from separate epiphyses, e.g. the trochanters of the femur. Bones increase in length by ossification continuing to extend into the epiphysial cartilage, which goes on growing in advance of the ossifying process. They increase in circumference by deposition of new bone, from the deep layer of the periosteum, on their external surfaces, and at the same time an absorption takes place from within, by which the medullary cavities are increased.

The permanent bone formed by the periosteum when first laid down is spongy in structure. Later the osteoblasts contained in its spaces form the concentric layers characteristic of the Haversian systems, and are included as bone-cells.

FIG. 36.—Part of a longitudinal section of the developing femur of a rabbit. (Klein and Noble Smith.)

Flattened cartilage-cells. *b*. Enlarged cartilage-cells. *c*, *d*. Newly formed bone. *e*. Osteoblasts. *f*. Giant-cells or osteoclasts. *g*, *h*. Shrunken cartilage-cells.

The number of ossific centres varies in different bones. Most of the short bones are ossified from a single centre. In the long bones there is a primary centre for the body, or diaphysis; and one or more secondary centres, or epiphyses, for each extremity. That for the body is the first to appear. The times of union of the epiphyses with the body vary inversely with the dates at which their ossifications

FIG. 37.—Osteoblasts and osteoclasts in the developing femur of a kitten. $\times 350$.

begin (with the exception of the fibula) and regulate the direction of the nutrient arteries of the bones. Thus, the nutrient arteries of the bones of the arm and forearm are directed towards the elbow, since the epiphyses at this joint become united with the bodies of the bones before those at the opposite extremities. In the lower limb, on the contrary, the nutrient arteries are directed away from the knee; that is, upwards in the femur, downwards in the tibia and fibula; and in them it is observed that the epiphyses at the upper end of the femur, and those at the lower ends of the tibia and fibula, unite first with the bodies. Where there is only one epiphysis, the nutrient artery is directed towards the other end of the bone.

Parsons* groups epiphyses under three headings, viz. (1) *pressure epiphyses*, appearing at the articular ends of the bones and transmitting 'the weight of the body from bone to bone'; (2) *traction epiphyses*, associated with the insertion of muscles and 'originally sesamoid structures though not necessarily sesamoid bones'; and (3) *atavistic epiphyses*, representing parts of the skeleton which at one time formed separate bones, but which have lost their function 'and only appear as separate ossifications in early life.'

The description here given of the development and growth of bone is in accordance with the generally accepted view. Macewen† has, however, given another account. He asserts that the osteoblasts are produced by division of the nuclei of the cartilage-cells, and that bone-formation is brought about by these cells, the periosteum taking no part in the process. He concludes that the function of the periosteum in the development of bone is mechanical, and is confined to limiting the degree of growth and deciding its direction.

Applied Anatomy.—It has been stated above that the bones increase firstly in length by ossification continuing to extend in the epiphysal cartilage, which goes on growing in advance of the ossifying process; and secondly in circumference by deposition of new bone from the deeper layer of the periosteum, on the external surface.

A careful study of osseous development is of the very greatest utility in the proper understanding of bone disease; and, moreover, an accurate knowledge of the blood-supply of a long bone has also many important bearings. The outer portion of the compact tissue being supplied by periosteal vessels which reach the bone through muscular attachments, it follows that where the muscular structures are well developed, and therefore amply supplied with blood, the periosteum will also be well nourished and the bones proportionately well developed in girth; this is well seen in strong muscular men with well-marked ridges on the bones. Conversely, if the muscular development be poor, the bones are correspondingly thin and light, and if from any cause a limb has been paralyzed

* *Journal of Anatomy and Physiology*, vols. xxxviii., xxxix., and xlii.

† *The growth of bone*, by Sir William Macewen.

from early childhood, the whole of the bones of that extremity are remarkable for their extreme thinness—that is to say, the periosteal blood supply has been insufficient to nourish that membrane, and consequently very little fresh osseous tissue has been added to the bones from the outside.

The best example of this condition is seen in connexion with the disease known as *infantile paralysis*, where a limb becomes paralyzed at a very early period of childhood, where the muscles become flaccid and atonic, and where the blood-supply is in consequence very greatly diminished. In such cases, although the limb does continue to grow in length from the epiphysal lines, its length is considerably less than on the normal side, owing to the imperfect nutrition; but the most striking feature about all the long bones of the limb is their remarkable tenuity, little or no addition having been made to their circumferences.

In cases where the periosteum has been separated from the compact tissue by extensive injury or inflammatory exudation, necrosis or death of the underlying portion of bone takes place owing to its blood-supply having been cut off, and the dead portion or *sequestrum* has to be separated.

Cases, however, occur where the inflammatory process affects the whole or a great portion of the diaphysis of a long bone; here extensive death of the affected portion takes place, and the condition goes by the name of *acute infective periostitis*. Where this occurs the body of the bone dies very rapidly, especially if the single nutrient artery be thrombosed at the same time. The pus which has formed beneath the periosteum is set free by timely incision, or bursts on the surface; the periosteum then falls back on the necrosed diaphysis and rapidly forms a layer of new periosteal bone, surrounding the sequestrum. This layer is called the *involucrum*, and the openings in it through which the pus escapes the *cloaca*. When the inflammatory process affects mainly the medullary canal, the condition is spoken of as *osteomyelitis*, and the two conditions very frequently coexist, and then go by the name of *acute infective necrosis of bone* or *acute diaphysitis*. When the medullary cavity is filled with pus, septic thrombosis of the veins in the Haversian canals takes place, and there is a very great danger of septic emboli being displaced and carried into the general circulation, thus setting up a fatal *pyæmia*. In fact, *pyæmia* is more frequently due to septic bone conditions than to any other cause.

In pre-antiseptic days, *pyæmia* frequently resulted from amputations, where the medullary canal of a long bone was opened by the saw cut. *Osteomyelitis* ensued, and if the patient survived, a tubular sequestrum of the divided shaft subsequently separated.

A proper knowledge of the epiphyses is of the utmost possible importance, and greatly simplifies many of the problems in the pathology of bone disease.

Speaking generally, the long bones have at either end an epiphysis from the cartilage of which growth occurs, and hence the body of the bone increases in length from both ends. In every case, however, one epiphysis is the more active, and also continues in its activity for a longer time. This *actively growing epiphysis* is always the one from which the nutrient foramen in the diaphysis points, and it unites to the diaphysis at a later date. It follows, therefore, that the increase in length of a bone is largely dependent on this epiphysis, and hence anything which interferes with the growth from this epiphysal line at any time prior to the union of the epiphysis with the diaphysis must result in a cessation of growth in length of that bone. Thus when dealing with disease in the neighbourhood of this actively growing epiphysis very great care should be taken not to excise or destroy its line of union with the diaphysis. These epiphyses are particularly prone to become the seat of tuberculous disease, which tends to attack especially the soft, highly vascular cancellous tissue.

Again, the actively growing epiphysal plate is the portion of a long bone which is in the vast majority of cases affected by tumour growth in bone, whether it be innocent or malignant, the former (e.g. *osteoma*) usually appearing about puberty, and the latter (e.g. *sarcoma*) usually towards the end of the active period of epiphysal growth.

Epiphysal growth, moreover, has to be considered by the surgeon when he is about to amputate in a child. If the amputation is being performed through a bone, the actively growing epiphysis of which is at the upper end (e.g. humerus and tibia), and which will continue to grow for several years, it will be necessary to make allowance for this and to cut the flaps long; as otherwise, owing to continued growth, the sawn end of the bone will ultimately project through the stump, and result in a condition known as '*conical stump*.' This requires removal of a further portion of the bone.

Premature synostosis or ossification at the epiphyses of the long bones, bringing to an end the process by which they normally increase in length, is one of the causes of dwarfism. Persons in whom this has occurred will have the head and trunk of normal size, but the legs and arms disproportionately short though often very stout and strong.

An inflammatory condition termed *acute epiphysitis* also occurs, although it is not so frequent as the acute infective conditions of the diaphysis, owing to the freer blood-supply of the epiphysis; in late years it has been shown that acute epiphysitis in children is very frequently the result of a pneumococcal infection, and it may pass on to complete separation of the epiphysis. In this connexion it is worthy of note that some of the epiphysal lines lie entirely within the capsules of their corresponding joints, in other cases

entirely without the capsules; and it must follow that in the former case the epiphysal disease, acute or chronic, becomes, *ipso facto*, practically synonymous with disease of that joint. The best examples of intraarticular epiphyses are those for the head of the femur and head of the humerus, and the vast majority of all cases of tuberculous disease of the hip start as a tuberculous epiphysitis about the intraarticular epiphysal plate of the femur; again, cases of acute septic arthritis of the shoulder- or hip-joints generally have their origins in these intraarticular epiphysal lines, and often result in separation of the affected epiphysis. Those of the other class, or extraarticular epiphyses, when diseased, do not tend to involve the neighbouring joint so readily; and it should be the surgeon's duty to keep the disease from involving the joint. For example, the trochanteric epiphysis of the femur is extraarticular as regards the hip-joint, and the epiphysal line of the head of the tibia is well below the level of the knee-joint, and should a chronic tuberculous abscess form in the latter situation, it should be attacked from the outside before it has time to spread up and involve the cartilage of the head of the tibia. It is therefore of great surgical interest to note in every case the relations which the various epiphysal lines bear to their respective joint capsules.

A knowledge of the exact periods when the epiphyses become joined to the shaft is often of great importance in medico-legal inquiries. It also aids the surgeon in the diagnosis of many of the injuries to which the joints are liable; for it not infrequently happens that, on the application of severe force to a joint, the epiphysis becomes separated from the diaphysis, and such injuries may be mistaken for fracture or dislocation. Examination with the x-rays is naturally of the greatest service in deciding whether epiphyses have or have not united, and whether they have been cracked or displaced by injury. •

THE CIRCULATING FLUIDS

The **circulating fluids** of the body are the blood and the lymph.

BLOOD

The blood is an opaque, rather viscid fluid, of a bright red or scarlet colour when it flows from the arteries, of a dark red or purple colour when it flows from the veins. It is salt to the taste, and has a peculiar faint odour and an alkaline reaction. Its specific gravity is about 1.059, and its temperature is generally about 37° C., though varying slightly in different parts of the body.

FIG. 38.—Human red blood-corpuscle 1500.

a. Seen from the surface. b. Seen in profile. c. Forming rouleaux
d. Rendered crenate by salt solution.

If a thin film of blood be examined under the microscope it is seen to consist of a faintly yellow fluid, the *plasma* or *liquor sanguinis*, in which are suspended numerous minute particles, the *blood-corpuscles*.

The **blood-corpuscles** are of three kinds: (1) coloured corpuscles or erythrocytes, (2) colourless corpuscles or leucocytes, (3) blood-platelets.

1. **Coloured or red corpuscles (erythrocytes)** are circular discs, biconcave in profile. The disc has no nucleus, but, in consequence of its biconcave shape, it presents, when seen on the flat, a central area which, when the more prominent peripheral zone of the

corpuscle is in focus, appears dark, and so simulates a nucleus (fig. 38, a). The corpuscles vary slightly in size even in the same drop of blood, but the average diameter of each is about 7.5 μ , and the thickness about 2 μ . Besides these there are certain smaller corpuscles of about one-half of the size just indicated; these are termed *microcytes*, and are very scarce in normal blood; in diseased conditions (e.g. anæmia), however, they are more numerous. It is to the aggregation of the red corpuscles that the blood owes its red hue, although when examined by

transmitted light their colour appears to be only a faint reddish yellow. The number of red corpuscles in a cubic millimetre of blood is about 5,000,000 in a man, and 4,500,000 in a woman. Power states that the red corpuscles of an adult would present an aggregate surface of about 3,000 square yards.

If the web of a living frog's foot be spread out and examined under the microscope, the blood is seen to flow in a continuous stream through the vessels, and the corpuscles show no tendency to adhere to each other or to the wall of the vessel. Doubtless the same is the case in the human body; but when human blood is drawn and examined on a slide, the corpuscles tend to collect into heaps like rouleaux of coins (fig. 38, c). During life the red corpuscles may be seen to change their shape under pressure so as to adapt themselves, to some extent, to the size of the vessel. They are, however, highly elastic, and speedily recover their shape when the pressure is removed. They are readily influenced by the medium in which they are placed. In 0.9 per cent. sodium chloride solution, which is isotonic with human blood-plasma, they are unaltered in shape. In hypotonic solutions they swell up and become globular owing to the passage of water from the surrounding

FIG. 39.—Human bone-marrow. Highly magnified.

medium into the corpuscle (*endosmosis*). In hypertonic solutions, e.g. 2 per cent. sodium chloride, water passes in the reverse direction (*exosmosis*) and the corpuscle shrinks and becomes crenated in appearance (fig. 38, d). The surface layer of the erythrocyte thus behaves as a membrane which is permeable to water, but not to salts (semi-permeable membrane), and, for this and other reasons, Schäfer believes that each corpuscle consists of an envelope containing the coloured substance, hæmoglobin. According to another view, the erythrocyte consists of a stroma or sponge work permeated by the hæmoglobin. The stroma, or envelope consists mainly of cholesterol, lecithin, and nucleoprotein.

The origin of the red corpuscles.—(1) In *early embryonic life* nucleated erythrocytes (*erythroblasts*) are formed in the 'blood-islands' of the vascular area. Certain mesodermic cells in these islands enlarge, and the nucleus of each subdivides, forming a number of daughter nuclei. The interior of the cell then becomes hollowed out, so that the nuclei, each surrounded by a certain amount of protoplasm, lie free in a fluid. The protoplasm of most of these nucleated fragments, which are known as *hæmoblasts*, becomes tinged with hæmoglobin, and in this way the erythroblasts are formed. By the fusion of adjacent hollowed cells and the intercommunication of the cavities containing the erythroblasts the blood-vessels are formed. After the appearance of the liver and spleen multiplication

of the nucleated blood-corpuscles goes on by mitotic division in the vascular spaces of these organs, as well as in the circulating blood itself. Ultimately the nuclei of the erythroblasts disappear, probably by atrophy, and in the eighth month of foetal life the red corpuscles are nearly all non-nucleated. (2) In *later embryonic life* the formation of non-nucleated erythrocytes takes place in the cells of the connective tissue. Coloured globules appear in the body of the cell, and are set free by the vacuolation of the cell substance around them, the vacuoles becoming fused so that the globules float in a fluid. Blood-vessels are formed by the union of adjacent cells, as in the mesoderm at an earlier period. (3) During *post-natal life* the formation of erythrocytes occurs in the red marrow of bones. The red marrow consists of a small quantity of connective tissue, blood-vessels, and numerous cells (fig. 39), a few of which are fat-cells, but the great majority are spherical, nucleated cells, the true 'marrow-cells.' These marrow-cells proper, or *myelocytes*, resemble the leucocytes of blood, and like them are amoeboid; they contain granules, either oxyphil, basiphil, or neutrophil in reaction. A number of eosinophil cells and a few basiphil cells are also present (see below). Among the marrow-cells may be seen smaller nucleated cells of a yellowish colour; these are the erythroblasts or *normoblasts* from which the red corpuscles are derived, and which may be regarded as descendants of the coloured nucleated corpuscles of the embryo. Erythrocytes are formed from these erythroblasts by the disappearance of the nucleus. Giant-cells (*myeloplaxes* or *megakaryocytes*) similar to the osteoclasts described in connexion with the development of bone, are also found in red marrow.

The **colourless corpuscles** or *leucocytes* are of various sizes. In human blood the majority are rather larger than the red corpuscles, and measure about 10μ in diameter. On the average from 7,000 to 12,000 leucocytes are found in each cubic millimetre of blood.

FIG. 40.—Varieties of colourless corpuscles found in human blood. $\times 1500$.

a. Eosinophil corpuscles. b. Polymorphonuclear leucocytes. c. Hyaline cell or macrocyte. d. Lymphocytes.

They consist of minute nucleated masses of protoplasm, and exhibit several varieties, which are differentiated from each other chiefly by the occurrence or non-occurrence of granules in their protoplasm, and by the staining reactions of these granules when present (fig. 40). (1) The most numerous and important are termed *polymorphonuclear* leucocytes; they are irregular in shape in the living condition, are possessed of the power of amoeboid movement, and are characterised by containing nuclei which often consist of two or three parts (multipartite) connected together by fine threads of chromatin. When at rest or dead, they are spherical in shape as a rule. The protoplasm is clear, and contains a number of very fine granules, which stain with acid dyes such as eosin, or with neutral dyes, and are therefore called *oxyphil* or *neutrophil*. They constitute 60 to 70 per cent. of the total number of the colourless corpuscles. (2) A second variety comprises from 1 to 4 per cent. of the leucocytes; they are larger than the previous kind, and are made up of coarsely granular protoplasm, the granules being highly refractile and grouped round single nuclei of horseshoe shape. The granules stain deeply with eosin, and the cells are therefore often termed *eosinophil* corpuscles. (3) The third variety is called the *hyaline* cell or macrocyte. This is usually about the same

size as the eosinophil cell, and, when at rest, is spherical in shape and contains a single round or oval nucleus. The protoplasm is free from granules, but is not quite transparent, having the appearance of ground glass. (4) The fourth kind is designated the *lymphocyte*, because it is identical with the cell derived from the lymph-glands, or other lymphoid tissue. They are the smallest of the leucocytes,

FIG. 41.—Human colourless blood-corpuscle, showing its successive changes of outline within ten minutes when kept moist on a warm stage. (Schiefeld.)

and each consists of a spheroidal nucleus with a very little surrounding protoplasm of a homogeneous nature. The third and fourth varieties together constitute from 20 to 30 per cent. of the colourless corpuscles, but of these two varieties the lymphocytes are by far the more numerous. Leucocytes having in their protoplasm granules which stain with basic dyes (*basophil*) have been described as occurring in human blood, but they are rarely found except in disease.

The colourless corpuscles are very various in shape in living blood (fig. 41), because many of them have the power of constantly changing their form by protruding finger-shaped or filamentous processes of their substance, by which they move and take up granules from the surrounding medium. In locomotion the corpuscle pushes out a process of its substance—a *pseudopodium*, as it is called—and gradually the rest of the body flows into it. In the same way when any granule or particle comes in its way the corpuscle protrudes a pseudopodium towards it, and then draws the particle into its own substance. By means of these amoeboid properties the cells have the power of wandering or emigrating from the blood-vessels by penetrating their walls and thus finding their way into the extravascular spaces. The solid chemical constituents of leucocytes are nucleoprotein, globulin, fat, cholesterol, lecithin, glycogen, and salts.

FIG. 42.—Blood-platelets. Highly magnified. (After Kopsch.) (From Schäfer's Essentials of Histology.)

The origin of the colourless blood-corpuscles.

—In *early embryonic life* leucocytes are developed from the haemoblasts already described. Some of these primitive blood-cells do not become coloured, but are converted into colourless blood-corpuscles. During *post-natal life* the lymphocytes are developed from the cells of lymphoid tissue in the lymph-glands, Malpighian corpuscles of the spleen, and elsewhere: polymorphonuclear corpuscles and eosinophil cells are derived from the myelocytes of red marrow. Some observers believe, however, that all other forms of leucocytes are developed ultimately from lymphocytes. Leucocytes may also multiply by division, which, in some cases at least, is amitotic.

The **blood-platelets** (fig. 42) are discoid or irregularly shaped, colourless, refractile bodies, much smaller than the red corpuscles. Each contains a central chromatin mass resembling a nucleus. Blood-platelets possess the power of amoeboid movement. When blood is shed they rapidly disintegrate and form granular masses, setting free *thrombokinas*, a substance which takes part in the production of fibrin and so is concerned in bringing about the coagulation of the blood. It is doubtful whether platelets exist normally in circulating blood.

LYMPH

Lymph is a transparent, colourless or slightly yellow fluid, which is conveyed into the blood by a set of vessels named *lymphatics*. These vessels arise in nearly all parts of the body as *lymph-capillaries*. They take up the fluid which has exuded

from the blood-capillaries for the nourishment of the tissue-elements, and return it into the veins. The greater number of these lymphatic vessels empty themselves into the *thoracic duct*, which ascends in front of the vertebral column and opens into the junction of the internal jugular and subclavian veins on the left side of the root of the neck. The remainder empty themselves into a smaller duct which ends in the corresponding veins on the right side of the neck.

Lymph is a watery fluid of sp. gr. about 1.015; it closely resembles the blood-plasma, but is more dilute. When it is examined under the microscope, leucocytes of the lymphocyte class are found floating in the transparent fluid; they are always increased in number after the passage of the lymph through lymphoid tissue, as in lymph-glands.

MUSCULAR TISSUE

Muscular tissue is composed of bundles of reddish fibres endowed with the property of contractility. There are three varieties of muscle, (1) *striped* or *voluntary*, (2) *unstriped* or *involuntary*, and (3) *cardiac*. The muscles which are concerned

FIG. 43.—Transverse section of human striped muscle-fibres.
× 255.

with the movements of the bony skeleton, the skeletal muscles, are composed of striped fibres, and are under the control of the will. The muscular coats of the stomach and intestines, uterus, bladder and blood-vessels, on the other hand, are formed of unstriped fibres, and their movements are involuntary. Some striped muscles, however, are not under voluntary control, namely, those forming the walls of the pharynx and upper part of the œsophagus; the ciliary muscle of the eye, though composed of unstriped fibres, is a voluntary muscle. Cardiac muscle is intermediate in position between the other two varieties. Its fibres are striped, but involuntary, and they differ from both striped and unstriped muscle in structure.

Striped fibres are arranged in bundles or *fasciculi*, in which the individual fibres are parallel to each other. Each fasciculus has a connective tissue sheath, called the *perimysium*, prolongations of which run into the bundle, binding the fibres together and constituting the *endomysium*. A muscle is composed of a number of fasciculi, held together and surrounded by connective tissue which is known as the *epimysium*. The fasciculi are of different sizes in different muscles, and are for the most part placed parallel to each other, though they usually converge towards the tendinous attachments. The connective tissue framework of the muscle contains the blood-vessels and nerves which supply it.

A *muscular fibre* may be said to consist of a soft contractile substance, enclosed in a tubular sheath named by Bowman the *sarcolemma*. The fibres are cylindrical or prismatic in shape (fig. 43), and are of no great length, not exceeding as a rule 40 mm. Their breadth varies in man from 0.01 mm. to 0.1 mm. As a rule, the fibres do not divide or anastomose; but occasionally, especially in the tongue and facial muscles, they may be seen to divide into several branches. In the substance of the muscle, the fibres end by tapering extremities which are joined to the ends of other fibres by the sarcolemma. Where a muscle joins its tendon, the sarcolemma covering the end of each muscle-fibre blends with a corresponding group of the fine fibres of the tendon. The muscular substance of the fibre can readily be made to retract from the point of junction. The areolar tissue between the fibres is prolonged more or less into the tendon, so as to form a kind of sheath around the tendon-bundles for a longer or shorter distance. When muscular fibres are attached to skin or mucous membranes, this sheath becomes continuous with the areolar tissue of these structures.

The *sarcolemma*, or tubular sheath of the fibre, is a transparent, elastic, and apparently homogeneous membrane of considerable toughness, so that it sometimes

remains entire when the included substance is ruptured. On the internal surface of the sarcolemma in mammalia, and also in the substance of the fibre in frogs, elongated nuclei are seen, and in connexion with these is a little granular protoplasm.

Upon examination of a voluntary muscular fibre by transmitted light, it is found to be marked by alternate light and dark bands or striæ, which pass transversely across the fibre (fig. 44). When examined by polarised light the dark bands are found to be doubly refracting (anisotropic), while the clear stripes are singly refracting (isotropic). The dark and light bands are of nearly equal breadth, and alternate with great regularity; they vary in breadth from about 1μ to 2μ . When the fibre is deeply focussed a dark line may be seen running in the middle of the clear stripe. This is known as *Dobie's line* or *Krause's membrane*. In fibres which are in the extended condition the dim stripe is often seen to be divided by a clearer line, *Hensen's line*.

Under high magnification there are indications that the striped muscle-fibre is made up of a large number of fibrils, known as *sarcostyles* or muscle-columns, together with an interfibrillar material, or *sarcoplasm* (fig. 45, B). When a fibre is treated with weak acid it becomes clearer, and the sarcoplasm is visible as fine, longitudinal, parallel lines. At the junction of the dim and clear stripes these lines often show bead-like enlargements in the extended condition of the fibre. In transverse sections the sarcostyles appear as minute, polygonal areas, each surrounded by clear sarcoplasm, which then appears to form a network. The small areas are known as *Cohnheim's areas*.

When the sarcostyles are separated by suitable methods it becomes evident that each exhibits alternate dim and clear portions, with *Dobie's* and *Hensen's* lines, and that the striped appearance of the fibre is due to the apposition of the corresponding segments of the fibrils of which it is composed.

Schäfer has worked out the minute anatomy of muscular fibre, particularly in the wing muscles of insects, which are peculiarly adapted for this purpose on account of the relatively large size of the sarcostyles and

FIG. 45.—A. Portion of a medium-sized human muscular fibre. Magnified nearly 800 diameters. B. Separated bundles of fibrils, equally magnified.

the ease with which they can be separated given by Schäfer is closely followed.

A sarcostyle may be said to be made up of successive portions, each of which is termed a *sarcomere*. The sarcomere is situated between two membranes of *Krause*, and consists of (1) a central dark part, which forms a portion of the dark band of the whole fibre, and (2) a clear area at either end, each forming, with the corresponding clear part of the adjacent sarcomere, the light band of the fibril. The central dark segment really consists of two parts, and when the fibre is stretched these two parts become separated from each other at the line of *Hensen* (fig. 46, A).

FIG. 44.—Striped muscle-fibres from the tongue of a cat. $\times 250$.

The clear areas are well marked in the extended sarcostyle, but in the contracted sarcostyle they are small or altogether absent (fig. 46, B).

The central dim portion, or *sarcous element*, does not lie free in the sarcomere, for when the sarcostyle is stretched, so as to render the clear portion visible, very fine lines, which are probably septa, may be seen running through it from the sarcous element to the membrane of Krause.

Schäfer explains these phenomena in the following way. He considers that each dim segment contains a number of longitudinal channels, which open into the clear part towards the membrane of Krause but are closed at the line of Hensen. When the muscular fibre contracts the clear part of the muscular substance passes into these channels or tubes, and is therefore hidden from sight, but at the same time it swells up the sarcous element and widens and shortens the sarcomere. When, on the contrary, the fibre is extended, this clear substance is driven out of the tubes and collects between the sarcous element and the membrane of Krause, and gives the appearance of the light part between these two structures; by this means it elongates and narrows the sarcomere.

Schäfer has shown that, if this view be correct, it harmonises the contraction of muscle with the amoeboid action of protoplasm. In an amoeboid cell there is, according to one view of the structure of protoplasm, a framework of spongioplasm,

FIG. 46.—Diagram of a sarcomere. (After Schäfer.)

A. In a moderately extended condition. B. In a contracted condition.

H. Line of Hense k, k Membranes of Krause. S.E. Sarcous element.

enclosing in its meshes a clear substance, hyaloplasm. Under stimulation the hyaloplasm passes into the pores of the spongioplasm; without stimulation it tends to pass out, as in the formation of pseudopodia. In muscle there is the same thing, viz. a framework of spongioplasm the substance of the dim segment: and this encloses a clear hyaloplasm, the clear substance of the sarcomere. During contraction of the muscle—i.e. under stimulation—this clear substance passes into the pores of the spongioplasm; while during extension of the muscle—i.e. when there is no stimulation—it tends to pass out of the spongioplasm. In this way the contraction is brought about: under stimulation the protoplasmic material (the clear substance of the sarcomere) recedes into the sarcous element, causing the sarcomere to widen out and shorten. The contraction of the muscle is merely the sum total of this widening out and shortening of these bodies.

Vessels and nerves of striped muscle.—The *capillaries* of striped muscle are very abundant, and form a sort of rectangular network, the branches of which run longitudinally in the endomysium between the muscular fibres, and are joined at short intervals by transverse anastomosing branches. In the red muscles of the rabbit dilatations occur on the transverse branches of the capillary network. The larger vascular channels, arteries and veins, are found only in the perimysium, between the muscular fasciculi. *Nerves* are profusely distributed to striped muscle. Their mode of termination is described in the chapter on Neurology. *Lymphatic vessels* do not occur in striped muscle, though they have been found in tendons and in the sheaths of the muscles.

Unstriped, plain, or involuntary muscle is found in the following situations—in the lower half of the œsophagus and the whole of the remainder of the gastro-

intestinal tube; in the trachea and bronchi; in the gall-bladder and common bile-duct; in the large ducts of the salivary and pancreatic glands; in the pelvis and calyces of the kidney, the ureter, bladder, and urethra; in the female sexual organs—viz. the ovary, the uterine tubes, the uterus (enormously developed in pregnancy), the vagina, the broad ligaments, and the corpora cavernosa of the clitoris; in the male sexual organs—viz. the Dartos of the scrotum, the ductus deferentes and epididymes, the vesiculæ seminales, the prostate, and the corpora cavernosa of the penis and urethra; in the capsule and trabeculæ of the spleen; in the mucous membranes, forming the muscularis mucosæ; in the skin, forming the Arrectores pilorum, and also in the sweat-glands; in the arteries, veins, and lymphatics; in the iris and the ciliary muscle.

Unstriated or plain muscle is made up of spindle-shaped cells (fig. 47), collected into bundles and held together by a cement-substance. These bundles are further aggregated into larger fasciculi, or sheets, bound together by ordinary connective tissue.

The cells are elongated, spindle-shaped, and nucleated, and are of various sizes, averaging from 40μ to 80μ in length, and 6μ to 7μ in breadth. On transverse section they are more or less polyhedral in shape, from mutual pressure.

FIG. 48.—Anastomosing muscular fibres of the heart seen in a longitudinal section. On the right the limits of the separate cells with their nuclei are exhibited somewhat diagrammatically.

Each presents a faint longitudinal striation and consists of an elastic cell-wall containing the contractile substance, and an oval or rod-like nucleus. A centriole lies close to the nucleus.* The fibres are attached to one another by a certain amount of interstitial cement-substance which reduces nitrate of silver, but in some regions, e.g. the muscular coats of the intestines, the muscle-cells are also connected by 'bridges' similar to those which occur in the prickles of the epidermis.

Sheets of smooth muscle frequently exhibit rhythmical contractions, which are more sluggish than the contractions of striped muscle and in many cases travel along the membrane in the form of waves. Such waves are well marked in the wall of the intestine. Contraction is often excited by a mechanical stimulus, as distension, for example, in the urinary bladder.

Cardiac muscular tissue.—The fibres of the heart differ very remarkably from those of other striped muscles. They are striated both transversely and longitudinally, but the striation, as compared with that of striped muscle, is faint and indistinct. The fibres are made up of quadrangular cells joined end to end so as

FIG. 47.—Muscle-fibres from the small intestine. From Quain's Elements of Anatomy, vol. ii. pt. i. Microscopic Anatomy.

A.—Complete cell. B. Broken cell showing delicate external layer.

to form a syncytium (fig. 48). Each cell contains a clear oval nucleus, situated near its centre. Many of the cells branch or divide, the subdivisions uniting with offsets from other cells, and thus producing an anastomosis of the fibres. The connective tissue between the bundles of fibres is much less than in ordinary striped muscle, and no sarcolemma has been proved to exist.

FIG. 49.—Purkinje's fibres from the sheep's heart.

A. In longitudinal section
B. In transverse section.

Purkinje's fibres (fig. 49).—Between the endocardium and the ordinary cardiac muscle are found, embedded in a small amount of connective tissue, peculiar fibres known as *Purkinje's fibres*. They are associated with the terminal distributions of the atrioventricular bundle. The fibres are very much larger in size than the cardiac cells and differ from them in several ways. In longitudinal section they are quadrilateral in shape, being about twice as long as they are broad. The central portion of each fibre contains one or more nuclei and is made up of granular protoplasm, with no indication of striation, while the peripheral portion is clear and has distinct transverse striations. The fibres are intimately connected with each other, possess no definite sarcolemma, and do not branch. They form a considerable portion of the moderator band in the heart of the sheep.

The **atrioventricular bundle** (see chapter on Angiology) is composed of cells which differ from ordinary cardiac muscle-cells in being more spindle-shaped. They are, moreover, more loosely arranged and have a richer vascular supply than the rest of the heart-muscle.

Development of muscle-fibres. Voluntary muscular fibres are developed from the mesoderm, the embryonic cells of which elongate, show multiplication of nuclei, and eventually become striated; the striation is first obvious at the side of the fibres, spreads around the circumference, and ultimately extends to the

centre. The nuclei, at first situated centrally, gradually pass out to assume their final position immediately beneath the sarcolemma. In the case of involuntary muscle the mesodermal cell assumes a pointed shape at the extremities and becomes flattened, the nucleus also lengthening out to its permanent rod-like form.

NERVOUS TISSUE

The **nervous tissues** of the body comprise the brain, the medulla spinalis or spinal cord, the cerebral, spinal, and sympathetic nerves, and the ganglia connected with them.

The nervous tissues are composed of *nerve-cells* and their various processes, together with a supporting tissue called *neuroglia*, which, however, is found only in the brain and medulla spinalis. Certain long processes of the nerve-cells are of special importance, and it is convenient to consider them apart from the cells; they are known as *nerve-fibres*.

To the naked eye a difference is obvious between certain portions of the brain and medulla spinalis, viz. the *grey substance*, and the *white substance*. The grey substance is largely composed of nerve-cells, while the white substance contains only their long processes, the nerve-fibres. It is in the former that nervous impressions are received, stored, and transformed into efferent impulses, and by the latter that they are conducted. Hence the grey substance forms the essential constituent of all the ganglionic centres, both those in the isolated ganglia and

those aggregated in the brain and medulla spinalis; while the white substance forms the bulk of the commissural portions of the nerve-centres and the peripheral nerves.

Neuroglia, the peculiar variety of connective tissue which binds together the true nervous constituents of the brain and medulla spinalis, consists of cells and fibres. Some of the cells (spider-cells) are stellate in shape, with ill-defined cell-body, and their fine processes become neuroglia fibres, which extend radially and unbranched (fig. 50, B) among the nerve-cells and fibres which they aid in supporting.

FIG. 50.—Neuroglia cells of the brain shown by Golgi's method. (After Andriezen.)
(From Schäfer's Essentials of Histology.)

A. Arborescent cell with branched processes.

B. Spider-cell with unbranched processes.

Other cells (arborescent cells) give off processes which branch repeatedly (fig. 50, A). Some of the fibres start from the epithelial cells lining the ventricles of the brain and central canal of the medulla spinalis, and pass through the nervous tissue, branching repeatedly, to end in slight enlargements on the pia mater. Thus, neuroglia is evidently a connective tissue in function, but it is not so in development; it is ectodermal in origin, whereas all other connective tissues are mesodermal.

Nerve-cells (fig. 51) are largely aggregated in the grey substance of the brain and medulla spinalis, but smaller collections of these cells also form the swellings, called *ganglia*, seen on many nerves. These latter are found chiefly upon the spinal and cerebral nerve-roots and in connexion with the sympathetic nerves.

Nerve-cells vary in shape and size, and have one or more processes. They may be divided for purposes of description into three groups according to the number of processes which they possess: (1) Unipolar cells are found in the spinal ganglia; the single process, after a short course, divides in a T-shaped manner (fig. 51). These cells are bipolar in embryonic life, but, as development proceeds, the two processes approach one another and become fused for a short distance. In the spinal ganglia of fish the cells are bipolar throughout life. (2) Bipolar cells (fig. 51) are found, in the adult, in the retina, and in the ganglion spirale and ganglion vestibulare of the acoustic nerve. In some cases where two fibres are apparently connected with a cell, one of the fibres is really derived from an adjoining nerve-cell and is passing to end in a ramification around a unipolar cell, or, again, it may be coiled spirally round the nerve-process which is issuing from the cell. (3) Multipolar cells are pyramidal or stellate in shape, and characterised by the numerous processes which issue from them. The processes are of two kinds: one of them is termed the *axis-cylinder process* or *axon* because it becomes the axis-

cylinder of a nerve-fibre (figs. 52, 53, 54). The others are termed the *protoplasmic processes* or *dendrons*; they begin to divide and subdivide as soon as they emerge from the cell, and finally end in minute twigs. The axons of certain multipolar

FIG. 51.—Various forms of nerve-cells.

cells found in the brain and medulla spinalis do not become nerve-fibres, but terminate by arborescence close to the cell-body. Such cells were called by Golgi multipolar cells of the second type.

The body of the nerve-cell is known as the *cyton*. In fixed and stained preparations it consists of a finely fibrillated protoplasmic material, of a reddish or yellowish-brown colour, which occasionally presents patches of a deeper tint, caused by the

FIG. 52.—Motor nerve-cell from the ventral horn of medulla spinalis of an ox. $\times 500$. The spindle-shaped Nissl's granules are shown. The dendrons and axon are broken off close to the cell.

Dendrons

Axon

aggregation of pigment-granules at one side of the nucleus, as in the substantia nigra and locus cæruleus of the brain. The protoplasm also contains peculiar angular granules, which stain deeply with basic dyes such as methylene blue; these are known as *Nissl's granules* (fig. 52). They extend into the dendritic processes but not into the axis-cylinder; the small clear area at the point of exit of the axon is termed the *cone of origin*. These granules disappear (*chromatolysis*) during fatigue or after section of the nerve-fibres connected with the cells. They are supposed to

represent a store of nervous energy, and in various mental diseases are deficient or absent. The nucleus is, as a rule, a large, well-defined body, with a relatively small amount of chromatin, and containing a well-marked nucleolus.

FIG. 53.—Pyramidal cell from the cerebral cortex of a mouse. Golgi method. (After Ramón y Cajal.)

FIG. 54.—Cell of Purkinje from the cerebellum. Golgi method. (Ramón y Cajal.)

a. Axon. b. Collateral. c and d. Dendrons.

In addition to the protoplasmic network described above, each nerve-cell may be shown to have delicate neurofibrils running through its substance (fig. 55); these fibrils are continuous with the fibrils of the axon, and are believed to convey nerve-impulses. Golgi has also described an extracellular network, which is probably a supporting structure.

Mott and Marinesco have shown that, when living nerve-cells are examined by the dark ground illumination method, neither Nissl's granules nor fibrils of any kind can be seen. The constancy of the occurrence of both these structures in fixed preparations, however, indicates that they represent something specific in the living cell.

Nerve-fibres are found universally in the peripheral nerves, and in the white substance of the brain and medulla spinalis. They are of two kinds—viz. *medullated* or *white* fibres, and *non-medullated* or *grey* fibres.

The *medullated fibres* form the white part of the brain and medulla spinalis, and also the greater part of every cerebral and spinal nerve, and give to these structures their opaque, white aspect. When perfectly fresh they appear to be homogeneous;

but soon after removal from the body each fibre presents, when examined by transmitted light, a double outline or contour, as if consisting of two parts (fig. 56). The central portion is named the *axis-cylinder*; around this is a sheath of fatty material, staining black with osmic acid, named the *white substance of Schwann* or *medullary sheath*, which gives to the fibre its double contour; and the whole is enclosed in a delicate membrane, the *neurolemma*, *primitive sheath*, or *nucleated sheath of Schwann* (fig. 57). Medullated nerve-fibres vary in diameter from 2μ to 16μ .

The *axis-cylinder* is the essential part of the nerve-fibre, and is always present; the medullary sheath and the neurolemma are occasionally absent, especially at the origin and termination of the nerve-fibre. The axis-cylinder undergoes no interruption from its origin in the nerve-centre to its termination, and must be

FIG. 55.—Nerve-cells of a kitten, showing neurofibrils. (Ramón y Cajal.)

a. Axon. b. Cyton. c. Nucleus. d. Neurofibrils.

regarded as a direct prolongation of a nerve-cell. Nerve-fibres in the white substance of the brain and medulla spinalis differ from those in the peripheral nerves in that they give off twigs known as *collaterals*. These arise from the main fibre at right angles to its course and run into the grey substance, where they terminate by arborisation. The axis-cylinder constitutes about one-half or one-third of the nerve-fibre, being greater in proportion in the fibres of the central organs than in those of the nerves. It is quite transparent, and is therefore indistinguishable in a perfectly fresh and natural state of the nerve. It is made up of exceedingly fine fibrils (figs. 57 and 58), which stain darkly with gold chloride, and at its termination may be seen to break up into these fibrils. The axis-cylinder is said by some to be enveloped in a special reticular sheath, which separates it from the medullary sheath, and is composed of a substance called *neurokeratin*. The more common opinion is that this network or reticulum is contained in the white substance of Schwann, and by some it is believed to be produced by the action of the reagents employed to show it.

The *medullary sheath* or *white substance of Schwann* (fig. 57) is regarded as being a fatty material in a fluid state, which insulates and protects, or possibly supplies nutriment to, the essential part of the nerve - the axis-cylinder. As a general rule its thickness is proportional to the size of the axis-cylinder, and is such that it forms about half of the total area of the cross section of the fibre. Its continuity is interrupted at regular intervals, giving to the fibre the appearance of constriction at these points; these are known as the *nodes of Ranvier* (figs. 56 and 57). The portion of nerve-fibre between two nodes is called an *internodal segment*. The neurolemma or primitive sheath is not interrupted at the nodes, but passes over them as a continuous membrane. Some observers, however, believe that the neurolemma of one internodal segment is connected with that of the adjacent segment at the node by cement-substance. If the fibre be treated with silver nitrate the reagent penetrates the neurolemma at the nodes, and, on exposure to light, reduction takes place, giving rise to the appearance of black crosses, *Ranvier's crosses*, on the axis-cylinder. There may also be seen transverse lines beyond the nodes termed *Frommann's lines* (fig. 59); the significance of these is not understood. In addition to these interruptions oblique clefts or *incisures* may be seen in the

g. 56.—Medullated nerve-fibres. $\times 350$.

FIG. 57.—Diagram of longitudinal sections of medullated nerve-fibres. Osmic acid.

medullary sheath, subdividing it into irregular portions, which are termed *medullary segments*, or *segments of Lantermann* (fig. 57); there is reason to believe that these clefts are artificially produced in the preparation of the specimens. Medullated nerve-fibres, when examined in the fresh condition, frequently present a beaded or varicose appearance, due to manipulation and pressure causing the oily matter to collect into drops; in consequence of the extreme delicacy of the primitive sheath even slight pressure will cause the transudation of the fatty matter, which collects as drops of oil outside the sheath.

FIG. 58.—Transverse sections of medullated nerve-fibres. Osmic acid.

in depressions in the white substance of Schwann, are nuclei surrounded by a small amount of protoplasm. The nuclei are oval and somewhat flattened, and one is

generally found in the middle of each internode. The primitive sheath is absent from the medullated fibres of the brain and medulla spinalis.

Wallerian Degeneration.—When nerve-fibres are cut across, the central ends of the fibres degenerate as far as the first node of Ranvier; but the peripheral ends degenerate simultaneously throughout their whole length. The axons break up into fragments and become surrounded by drops of fatty substance which are formed from the breaking down of the medullary sheath. The nuclei of the primitive sheath proliferate, and finally

FIG. 59.—Medullated nerve-fibres stained with silver nitrate.

FIG. 60.—A small branch from the sympathetic of a mammal.

a. Two small medullated nerve-fibres among a number of non-medullated nerve-fibres. b.

absorption of the axons and fatty substance occurs. If the cut ends of the nerve be sutured together regeneration of the nerve-fibres takes place by the downgrowth of axons from the central end of the nerve. At one time it was believed that the regeneration was peripheral in origin, but this has been disproved, the proliferated nuclei in the peripheral portions taking part merely in the formation of the so-called scaffolding along which the new axons pass.

Non-medullated fibres.—Most of the fibres of the sympathetic system, and some of the cerebrospinal, consist of the grey or gelatinous nerve-fibres—*fibres of Remak* (fig. 60). Each of these consists of an axis-cylinder to which nuclei are applied at intervals. These nuclei are believed to be in connexion with a delicate sheath corresponding with the neurolemma of the medullated nerve-fibre. In external appearance the non-medullated nerve-fibres are semitransparent and grey or yellowish-grey. The individual fibres vary in size, generally averaging about half the size of the medullated fibres.

EMBRYOLOGY

THE term **Embryology**, in its widest sense, comprises the various changes which take place during the growth of an animal from the egg to the adult condition; it is, however, usually restricted to the phenomena which occur before birth.

In vertebrate animals the development of a new being can only take place when a female germ-cell or *ovum* has been fertilised by a male germ-cell or *spermatozoon*. The ovum is a nucleated cell, and the complicated changes by which the various tissues and organs of the body are formed from it, after it has been fertilised, are the result of two general processes, viz. *segmentation* and *differentiation* of cells. Thus, the fertilised ovum undergoes repeated segmentation into a number of cells which at first closely resemble one another, but are, sooner or later, differentiated into two groups: (1) *somatic cells*, the function of which is to build up the various tissues of the body; and (2) *germinal cells*, which are destined for the perpetuation of the species.

Having regard to the main purpose of this work, it is impossible, in the space available in this chapter, to describe or illustrate fully, all the changes which occur during the development of the human body. Only the principal facts are given, and the student is referred for further details to one or other of the text-books * on human embryology.

THE OVUM

The ova are developed from the primitive germ-cells which are situated in the substance of the ovaries; each primitive germ-cell gives rise, by repeated divisions, to a number of smaller cells termed *oogonia* from which the *ova* or *primary oöcytes* are developed.

Human ova measure about 0.2 mm. in diameter, and are contained within the Graafian follicles of the ovaries †; as a rule each follicle contains a single ovum, but sometimes two or more are present. By the enlargement and subsequent rupture of a follicle at the surface of the ovary, an ovum is liberated and enters the uterine tube through which it is conveyed to the cavity of the uterus. Unless it be fertilised it is discharged from the uterus, but if fertilisation takes place it is retained there and is developed into a new being.

In appearance and structure the ovum (fig. 61) differs little from an ordinary cell, but distinctive names have been applied to its several parts; thus, the cell-substance is known as the *yolk* or *cytoplasm*, the nucleus as the *germinal vesicle*, and the nucleolus as the *germinal spot*. The ovum has a thick, transparent envelope named the *zona striata* or *zona pellucida*, and when the ovum is liberated from the Graafian follicle, several layers of cells, derived from those of the follicle, adhere to the outer surface of the *zona radiata*, and collectively constitute the *corona radiata*.

The **yolk** comprises (1) the *cytoplasm* of the ordinary animal cell with its spongioplasm and hyaloplasm; this is frequently termed the *formative yolk*; (2) the *deuterooplasm* or *nutritive yolk*, which consists of numerous rounded granules of fatty and albuminoid substances imbedded in the cytoplasm. • In the mammalian ovum the deuterooplasm is extremely small in amount, and is of service in nourishing the

† See description of the ovary under Splanchnology.

embryo in the early stages of its development only, whereas in the egg of the bird there is sufficient to supply the chick with nutriment throughout the whole period of incubation. Its mode of distribution within the egg varies in different animals; in some it is almost uniformly dispersed throughout the cytoplasm; in some it is centrally placed and surrounded by the cytoplasm; in others it is accumulated at the lower pole of the ovum, while the cytoplasm occupies the upper pole. A *centrosome* and *centriole* are present and lie in the immediate neighbourhood of the nucleus.

FIG. 61.—Human ovum examined fresh in the liquor folliculi. $\times 500$. (Waldeyer.)

The zona pellucida is seen as a thick clear girdle surrounded by the cells of the corona radiata. The ovum shows a central granular deuterooplasmic area and a peripheral clear layer, and encloses the germinal vesicle, in which the germinal spot is seen.

The **nucleus** or **germinal vesicle** is a large spherical body which at first occupies a nearly central position, but becomes eccentric as the growth of the ovum proceeds. Its structure is that of an ordinary cell-nucleus, viz. it consists of a reticulum or karyomitome the meshes of which are filled with karyoplasm, while connected with, or imbedded in, the reticulum are a number of chromatin masses or chromosomes, which may present the appearance of a skein or may assume the form of rods or loops. The nucleus is enclosed by a delicate nuclear membrane, and contains in its interior a well-defined nucleolus or germinal spot.

COVERINGS OF THE OVUM

The **zona striata** or **zona pellucida** (fig. 61) is a thick membrane, which, under the higher powers of the microscope, is seen to be radially striated. It is not yet determined whether the zona striata is a product of the cytoplasm of the ovum or of the cells of the corona radiata, or of both.

The *corona radiata* (fig. 61) consists of two or three strata of cells which are derived from the cells of the Graafian follicle, and adhere to the outer surface of the zona striata when the ovum is set free from the follicle; the cells are radially arranged around the zona, those of the innermost layer being columnar in shape. The cells of the corona radiata soon disappear; in some animals they secrete, or are replaced by, a layer of protein, which may assist in protecting and nourishing the ovum.

The phenomena attending the discharge of the ova from the Graafian follicles are described with the anatomy of the ovaries.

MATURATION OF THE OVUM

Before an ovum or primary oöcyte can be fertilised it must undergo a process of *maturation* or *ripening* (fig. 62). This process consists essentially of a heterotypical division of the ovum into two cells, followed by a homotypical division of the two cells into four; the heterotypical division occurs before the ovum is liberated

FIG. 62.—Formation of polar bodies in *Asterias glacialis*.
(Slightly modified from Hertwig.)

In fig. I the polar spindle (*sp*) has advanced to the surface of the egg. In fig. II a small elevation (*pb'*) is formed which receives half of the spindle. In fig. III the elevation is constricted off, forming the first polar body (*pb'*), and a second spindle is formed. In fig. IV is seen a second elevation which in fig. V has been constricted off as the second polar body (*pb''*). Out of the remainder of the spindle (*f.pn* in fig. VI) the female pronucleus is developed.

from the ovarian or Graafian follicle, the homotypical division usually after the spermatozoön has penetrated the zona striata. Three of the four cells are small, incapable of further development, and are named *polar bodies* or *polocytes*. The fourth cell is large; it is named the *mature ovum*, and is devoid of a centrosome. Its nucleus, as the result of the heterotypical division, contains only half the number of chromosomes which were present in the nucleus of the primary oöcyte. The nucleus of the mature ovum is named the *female pronucleus*.

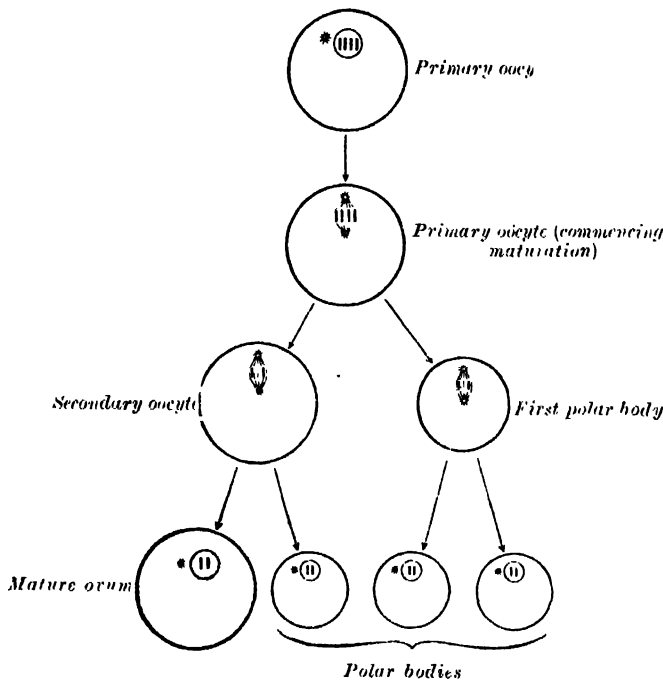

The process of maturation has not been observed in the human ovum, but has been carefully studied in the ova of some of the lower animals, to which the following description applies.

It was pointed out on page 2 that the number of chromosomes found in the nucleus is constant for all the cells in an animal of any given species, and that in man the number is probably twenty-four.* This applies not only to the somatic cells but to the primitive ova and their descendants. For the purpose of illustrating the process of maturation a species may be taken in which the number of nuclear chromosomes is four (fig. 63). If an ovum from such be observed at the beginning of the maturation process, the usual achromatic spindle is seen lying close to and parallel with the surface of the ovum, with the four chromosomes arranged at its

* H. von Winiwarter maintains that the number of chromosomes in the immature ovum is forty-eight, and in the primary spermatoöyte, forty-seven.

equator. The spindle then rotates so that its long axis is radial, and the first or heterotypical division takes place; two chromosomes pass to either end of the spindle, those at the periphery producing a surface elevation which is constricted off as the *first polar body*. The other two chromosomes are retained in the ovum, which is now termed a *secondary oöcyte*. Without passing through a resting stage the secondary oöcyte undergoes homotypical division, the two chromosomes each dividing into two, which travel to the ends of the spindle. A *second polar body* is

FIG. 63.—Diagram showing the reduction in number of the chromosomes in the process of maturation of the ovum.

segmented off, and the *mature ovum*, with two chromosomes gathered into a newly formed nucleus, remains. The first polar body frequently divides in a homotypical manner while the second is being formed, and as a final result four cells are produced, viz. the mature ovum and three polar bodies, each of which contains two chromosomes, i.e. half the number present in the nuclei of the somatic cells of members of the same species.

THE SPERMATOZOÖN

The spermatozoa or male germ-cells are developed in the testes and are present in enormous numbers in the seminal fluid; each consists of a small but greatly modified cell. The human spermatozoön possesses a head, a neck, a connecting piece or body, and a tail (fig. 64).

The **head** is ovoid or elliptical, but flattened, so that when viewed in profile it is pear-shaped. Its anterior two-thirds are covered by a layer of modified protoplasm, named the *head-cap*, which ends anteriorly in a sharp edge. In some animals (e.g. the salamander), the head-cap is prolonged into a barbed spear-like process (*acrosome* or *perforator*), which probably facilitates the entrance of the spermatozoön into the ovum.

The **neck** is less constricted in the human spermatozoön than in those of some of the lower animals. The *anterior centriole* is situated at the junction of the head and neck, and behind it is a band of homogeneous substance.

The **connecting piece** or **body** is rod-like, and is limited behind by a *terminal disc* or *ring*. The *posterior centriole* is placed at the junction of the body and neck,

and from it an *axial filament*, surrounded by a sheath, runs backwards through the body and tail. In the body the sheath of the axial filament is encircled by a *spiral thread*, around which is an envelope containing mitochondria granules, and termed the *mitochondrial sheath*.

The *tail* consists of the axial thread or filament, surrounded by a thin protoplasmic sheath; the terminal portion or *end-piece* of the tail is composed of the axial filament only.

Krause gives the length of the human spermatozoön as between 52μ and 62μ , the head measuring $4-5\mu$, the connecting piece 6μ , and the tail from 41μ to 52μ .

FIG. 64.—Human spermatozoa, highly magnified. A. Profile view. B. Surface view. (After Retzius.) C. Diagrammatic representation of the head, neck and connecting piece, more highly magnified. (Modified from Meeves.)

By virtue of their tails, which act as propellers, the spermatozoa are capable of free movement, and if placed in favourable surroundings (e.g. in the female passages) will retain their vitality and fertilising power for several days. In certain animals (e.g. bats) it has been proved that spermatozoa retained in the female passages for several months are capable of fertilising.

The spermatozoa are developed from the primitive germ-cells which have become imbedded in the testes, and the stages of their development are very similar to those of the maturation of the ovum. The primary germ-cells undergo division and produce a number of cells termed *spermatogonia*, and from these the *primary spermatocytes* are derived. Each primary spermatocyte undergoes a heterotypical division into two *secondary spermatocytes*, in the nuclei of which the number of chromosomes is reduced by half, and each secondary spermatocyte a homotypical division into two *spermatids* or young spermatozoa; from this it will be seen that each primary spermatocyte gives rise to *four* spermatozoa.

Interesting changes occur during the conversion of the spermatid into the spermatozoön (fig. 65). The two centrioles are at first placed tangentially to the surface of the spermatid but soon assume a radial position so that one lies deeper than the other; the deeper one forms the anterior centriole of the neck. The axial filament grows out from the superficial centriole which divides into two parts; the anterior part forms the posterior centriole of the neck, and the posterior part,

which is ring-like, migrates to the distal end of the connecting piece of body and there forms the terminal disc or ring, through which the axial filament passes. The nucleus of the spermatid forms the head of the spermatozoon, and the cytoplasm,

FIG. 65.—Transformation of spermatid into spermatozoon. (Diagrammatic.)
(Modified from Meeves.)

the investing sheath of the body and tail. The centrosphere moves away from the centrioles to the opposite side of the nucleus and is converted into the head-cap (acrosome).

On comparing the development of the spermatozoon with the maturation of the ovum (fig. 66) it will be observed that the primary spermatocyte gives rise to two

FIG. 66.—Scheme showing analogies in the process of maturation of the ovum and the development of the spermatids (young spermatozoa).

secondary spermatocytes, and the primary oocyte to the secondary oocyte and the first polar body; the two secondary spermatocytes give origin to four spermatozoa, and the secondary oocyte and first polar body to four cells, the mature ovum and three polar bodies. In the development of the spermatozoon, as in the maturation

of the ovum, there is a reduction of the nuclear chromosomes to one-half of those present in the primary spermatocyte. But here the similarity ends, for it must be noted that the four spermatozoa are of equal size, and each is capable of fertilising a mature ovum, whereas the three polar bodies are much smaller than the mature ovum, incapable of further development, and may be regarded as abortive ova.

FERTILISATION OF THE OVUM

Fertilisation consists in the union of the spermatozoön with the mature ovum (fig. 67). Nothing is known regarding the fertilisation of the human ovum, but the various stages of the process have been studied in other mammals, and from the knowledge so obtained it is believed that fertilisation of the human ovum takes place in the lateral or ampullary part of the uterine tube. The fertilised ovum is then conveyed along the tube to the cavity of the uterus—a journey probably

FIG. 67.—The process of fertilisation in the ovum of a mouse. (After Sobotta.)

occupying seven or eight days, and during which the ovum loses its corona radiata and zona striata and undergoes segmentation. Sometimes the fertilised ovum is arrested in the uterine tube, and there undergoes development, giving rise to a *tubal pregnancy*; or it may fall into the abdominal cavity and produce an *abdominal pregnancy*. Occasionally the ovum is not expelled from the Graafian follicle when the latter ruptures, but is fertilised within the follicle and produces what is known as an *ovarian pregnancy*. Under normal conditions only one spermatozoön enters the yolk and takes part in the process of fertilisation. At the point where the spermatozoön is about to enter, the yolk is drawn out into a conical elevation, termed the *cone of attraction*. As soon as the spermatozoön has penetrated the yolk, the peripheral portion of the latter is transformed into a membrane, the *vitelline membrane*, which prevents the entrance of additional spermatozoa. Occasionally a second spermatozoön may enter the yolk, thus giving rise to a condition of *poly-spermy*; when this occurs the ovum usually develops in an abnormal manner and

gives rise to a monstrosity. Having pierced the yolk, the spermatozoön loses its tail, while its head and connecting piece assume the form of a nucleus containing a cluster of chromosomes. This constitutes the *male pronucleus*, and associated with it there are a centrosome and centriole. The male pronucleus passes more deeply into the yolk, and the granules of the cytoplasm surrounding it become radially arranged. The male and female pronuclei migrate towards each other, and, meeting near the centre of the yolk, fuse to form the *segmentation nucleus* which thus contains both male and female nuclear substance; the former transmits the individualities of the paternal, the latter those of the maternal ancestors, to the future embryo. By the union of the male and female pronuclei the number of chromosomes is restored to that present in the nuclei of the somatic cells.

FIG. 68.—First stages of segmentation of a mammalian ovum; semidiagrammatic. (From a drawing by Ailen Thomson.)

z.p. Zona striata. p.gl. Polar bodies. a. Two-cell stage. b. Four-cell stage. c. Eight-cell stage. d, e. Morula stage.

In some insects the primary oöcyte contains twenty-four chromosomes, and the primary spermatocyte, twenty-three. The mature ovum and the polar bodies each contain twelve chromosomes, while half the spermatozoa contain twelve, and the other half, eleven. It is maintained that if the mature ovum be fertilised by a spermatozoön with eleven chromosomes, the resulting embryo is a male, but if it be fertilised by a spermatozoön with twelve chromosomes, a female embryo is produced.

SEGMENTATION OF THE FERTILISED OVUM

The early segmentation of the human ovum has not yet been observed, but from what is known to occur in other mammals it may be regarded as certain that the process starts immediately after fertilisation, i.e. while the ovum is in the uterine tube. The segmentation nucleus exhibits the usual mitotic changes, and these are succeeded by a division of the fertilised ovum into two cells of nearly equal size.*

* In the mammalian ova the nutritive yolk or deuteroplasm is small in amount and uniformly distributed throughout the cytoplasm; such ova undergo *complete* division during the process of segmentation, and are therefore termed *holoblastic*. In the ova of birds, reptiles, and fishes, where the nutritive yolk forms by far the larger portion of the egg, the cleavage is limited to the formative yolk, and is therefore only *partial*; such ova are termed *meroblastic*. Again, it has been observed, in some of the lower animals, that the pronuclei do not fuse but merely lie in apposition. At the commencement of the segmentation process the chromosomes of the two pronuclei group themselves around the equator of the nuclear spindle and then divide; an equal number of male and female chromosomes travel to the opposite poles of the spindle, and thus the male and female pronuclei subscribe equal shares of chromatin to the nuclei of the two cells which result from the subdivision of the fertilised ovum.

The process is repeated again and again, so that the two cells are succeeded by four, eight, sixteen, thirty-two, and so on, with the result that a mass of cells is found within the zona striata, and to this mass the term *morula* is applied (fig. 68). The cells of the morula, at first closely aggregated, soon arrange themselves into an outer or peripheral layer, the *trophoblast*, which takes no part in the formation

FIG. 69.—Blastodermic vesicle of *Vespertilio murinus*. (After van Beneden.)

FIG. 70.—Section through embryonic disc of *Vespertilio murinus*. (After van Beneden.)

FIG. 71.—Section through embryonic disc of *Vespertilio murinus* to show the formation of the amniotic cavity. (After van Beneden.)

of the embryo proper, and an *inner cell-mass*, from which the embryo is developed. Fluid collects between the trophoblast and the greater part of the inner cell-mass, and thus the morula is converted into a vesicle which is named the *segmentation cavity* (fig. 69). The inner cell-mass remains in contact, however, with the trophoblast at one pole of the ovum; this is named the *embryonic pole*, since it indicates the situation where the future embryo will be developed. In the human ovum (figs. 72 to 74) the segmentation cavity is occupied by delicate strands of mesoderm

(magma réticulé or primitive mesoderm). The fibrils of the magma réticulé are continuous with those of the chorionic mesoderm, and its tissue is identical with the mesoderm of the chorion (Mall). Clefts appear in the magma réticulé and run together to form the *extra-embryonic cœlom*, which at first assumes the form of two slit-like clefts, one on either side of the embryonic disc (fig. 74).

The trophoblast differentiates into two strata: an outer, the *syncytium* or *syncytiotrophoblast*, consisting of a layer of protoplasm studded with nuclei, but showing no evidence of subdivision into cells; and an inner, the *cytotrophoblast* or *layer of Langhans*, in which the cell-outlines are defined. As already stated, the trophoblast takes no share in the formation of the embryo proper; it forms the ectoderm of the chorion and plays an important part in the imbedding of the ovum in the uterine mucous membrane, and in the development of the placenta. The inner cell-mass divides into a dorsal, ectodermal, and a ventral, entodermal, part. Spaces appear between the cells of each part and coalesce to form a cavity the

FIG. 72.—Diagram showing first differentiation of inner cell-mass.

FIG. 73.—Diagram showing early stages in the formation of amnion and archenteron.

FIG. 74.—Diagram showing commencing formation of extra-embryonic cœlom.

cavity in the ectodermal part is named the *amniotic cavity*, that in the entodermal part, the *archenteron* (figs. 72, 73). The floor of the amniotic cavity is formed by the *embryonic disc* composed of a layer of prismatic cells, the *embryonic ectoderm*, which is in apposition with the entoderm of the archenteron.

Formation of the mesoderm—the primitive streak.—The development of the mesoderm has not been observed in the human ovum, seeing that it is already present in the youngest human ova that have been examined. From what has been observed in other animals it may be concluded that the primitive streak is its principal source. The embryonic disc becomes oval and then pear-shaped. Near its narrow, posterior end an opaque streak, the *primitive streak* (fig. 75), makes its appearance and extends along the middle of the disc for a considerable part of its length; at the anterior end of the streak there is a knob-like thickening of the ectoderm termed *Hensen's knot*. A shallow groove, the *primitive groove*, appears on the surface of the streak, and the anterior end of this groove communicates with the archenteron through an aperture named the *blastopore*. The primitive streak is produced by a thickening of the axial part of the ectoderm, the cells of which multiply and blend with those of the subjacent entoderm (fig. 76, III, IV, V). From the primitive streak a third layer of cells, the *mesoderm*, extends between the ectoderm and entoderm.

The extension of the mesoderm takes place throughout the whole of the embryonic and extra-embryonic areas of the ovum, except in certain regions. One of these is seen immediately in front of the neural tube. Here the mesoderm grows forwards in the form of two crescentic masses, which meet in the middle line so as to enclose an area which is devoid of mesoderm. Over this area the ectoderm and entoderm are in contact with each other and constitute a thin membrane, the *buccopharyngeal membrane*, which forms a septum between the stomodæum or primitive mouth and the fore-gut or head-end of the primitive digestive tube. Where the lateral crescents of mesoderm meet in front of the buccopharyngeal membrane, the pericardium is afterwards developed, and this region is therefore designated the *pericardial area*. At the hind end of the embryo the ectoderm and entoderm are also in contact, and here they form the *cloacal membrane*.

The embryonic disc now consists of three layers, named from without inwards, ectoderm, mesoderm, and entoderm; each has distinctive characteristics and gives rise to certain tissues of the body.

FIG. 75.—Surface view of embryo of *Hylobates concolor*. (After Selenka.)
(From Quain's Elements of Anatomy, vol. i. Embryology.)

The amnion has been opened to expose the embryonic disc.

The **ectoderm** consists of columnar cells, which are, however, somewhat flattened or cubical towards the margin of the embryonic disc. It forms the whole of the nervous system, the epidermis of the skin, the lining cells of the sebaceous, sudoriferous and mammary glands, the hairs and nails, the epithelium of the nose and adjacent air-sinuses, and that of the cheeks and roof of the mouth. From it also are derived the anterior lobe of the hypophysis cerebri, the epithelium of the cornea, conjunctiva, and lacrimal glands, the neuro-epithelium of the sense-organs, and the enamel of the teeth.

The **entoderm** consists at first of flattened cells, which subsequently become columnar. It forms the epithelial lining of the whole of the digestive tube excepting part of the mouth and pharynx and the terminal part of the rectum (which are lined by involutions of the ectoderm), the lining cells of all the glands which open into the digestive tube, including those of the liver and pancreas, the epithelium of the auditory tube and tympanic cavity, of the trachea, bronchi, and air-cells of the lungs, of the urinary bladder and part of the urethra, and that which lines the follicles of the thyroid gland and thymus.

The **mesoderm** consists of loosely arranged branched cells surrounded by a considerable amount of intercellular fluid. From it the remaining tissues of the

FIG. 76.—Series of transverse sections through the embryonic disc of *Tarsius*. (After Hubrecht.) (From Quain's Elements of Anatomy, vol. i. Embryology.)

Section I passes through the disc, in front of Hensen's knot, and shows only the ectoderm and entoderm. Sections II, III, and IV pass through Hensen's knot, which is seen in V tapering away into the primitive streak. In III, IV, and V the mesoderm is seen springing from the keel-like thickening of the ectoderm, which in III and IV is observed to be continuous into the entoderm.

body are developed. The endothelial lining of the heart and blood-vessels and the blood-corpuscles are, however, regarded by some as being of entodermal origin.

As the mesoderm spreads between the ectoderm and entoderm it is separated for a time into lateral halves by the neural tube and notochord, presently to be described. A longitudinal groove appears on the dorsal surface of either half and divides it into the *paraxial mesoderm* which adjoins the neural tube and notochord, and is subsequently divided into the primitive segments, and a lateral portion, the *lateral mesoderm*. The mesoderm in the floor of the longitudinal groove between the paraxial and the lateral mesoderm, is known as the *intermediate cell-mass*; the genito-urinary organs are developed in it, and for this reason it is sometimes named the *nephrogenic cord*. The lateral mesoderm splits into two layers, an outer or *somatic*, which adheres to the inner surface of the

FIG. 77.—Diagram showing extension of mesoderm.

ectoderm, and with it forms the *somatopleure*; and an inner or *splanchnic*, which adheres to the entoderm, and with it forms the *splanchnopleure* (figs. 79, 82). The space between the two layers of the lateral mesoderm is termed the *cælon*.

THE NEURAL GROOVE AND TUBE

In front of the primitive streak two longitudinal ridges, caused by a thickening and upfolding of the ectoderm, make their appearance, one on either side of the middle line (fig. 79). These are named the *neural folds*; they commence near the anterior end of the embryonic disc, where they are continuous with each other, and gradually extend backwards, one on either side of the anterior end of the primitive streak. Between the neural folds is a shallow median groove, the *neural groove* (figs. 79, 80). This groove gradually deepens, and the edges of the folds meet and coalesce in the middle line and convert it into a closed tube, the *neural tube* or *canal* (fig. 82), the ectodermal wall of which forms the rudiment of the nervous system. By the coalescence of the neural folds over the anterior end of the primitive streak, the blastopore no longer opens on the surface but into the neural tube, and thus a transitory communication, named the *neurenteric canal*, is established between the neural and primitive digestive tubes. Closure of the neural groove occurs first in the region of the hind-brain, and from there extends forwards and backwards; towards the end of the third week the anterior opening (*anterior neuropore*) of the tube closes, and forms a recess which is in contact, for a time, with the overlying ectoderm; about the same time the posterior opening or *posterior neuropore* is closed. Subsequently the paraxial mesoderm grows round the neural tube, and separates it from the overlying ectoderm. Before the neural groove is closed a ridge of ectodermal cells appears along the prominent margin of each neural fold; this is termed the *neural crest* or *ganglion-ridge* (fig. 78), and from it the spinal and cerebral nerve-ganglia, the ganglia of the sympathetic nervous system, and the chromaffin bodies are developed.

FIG. 78.—Two stages in the development of the neural crest in the human body (Lenhossek.)

The cephalic end of the neural groove exhibits several dilatations, the cavities of which, when the tube is closed, assume the form of three vesicles; these constitute the three primary cerebral vesicles, and correspond respectively to the future *prosencephalon* (fore-brain), *mesencephalon* (mid-brain), and *rhombencephalon* (hind-brain) (fig. 81). The walls of the vesicles are developed into the nervous tissue and neuroglia of the brain, and the cavities of the vesicles are modified to form

the ventricles of the brain. The remainder of the neural tube forms the *medulla spinalis* or *spinal cord*; its ectodermal wall forms the nervous and neuroglial elements and its cavity the central canal of the medulla spinalis.

THE NOTOCHORD

The **notochord** (fig. 82) constitutes the foundation of the axial skeleton, since around it the segments of the vertebral column are formed; its appearance synchronises with that of the neural tube. It grows forwards as a rod of cells from the anterior end of the primitive streak, and is at first intimately connected with the entoderm underlying the neural groove. It soon separates from the entoderm, and the separation is later emphasised by the mesoderm which grows medialwards and surrounds it. When fully formed it extends throughout the length of the future vertebral column, and its cephalic end reaches as far as the anterior part of the mid-brain, where it ends in a hook-like extremity in the region of the future dorsum sellæ of the sphenoidal bone. From the mesoderm surrounding the neural tube and notochord, the skull, the vertebral column, and the membranes of the brain and medulla spinalis are developed.

THE PRIMITIVE SEGMENTS

Towards the end of the second week transverse segmentation of the paraxial mesoderm begins, and converts it into a series of well-defined, more or less cubical masses, the *primitive segments* (figs. 81, 82, and 83), which extend from the occipital region of the skull along the entire length of the trunk on either side of the middle line. Each segment contains a central cavity (*myocœl*) which, however, is soon filled with angular and spindle-shaped cells.

The primitive segments lie immediately under the ectoderm on the lateral aspect of the neural tube and notochord, and are connected to the lateral mesoderm by the *intermediate cell-mass*. Those of the trunk are divisible into the following groups, viz. : cervical 8, thoracic 12, lumbar 5, sacral 5, and coccygeal from 5 to 8. Those of the occipital region of the head are usually described as being four in number. In mammals primitive segments of the head can only be recognised in the occipital region, but a study of the lower vertebrates leads to the belief that they are present also in the anterior part of the head, and that altogether nine segments are represented in the cephalic region.

FIG. 80.--Human embryo—length 2 mm. Dorsal view, with the amnion laid open. $\times 30$. (After Graf Spee.)

FORMATION OF THE EMBRYO

The embryo increases rapidly in size, but the circumference of the embryonic disc, or line of meeting of the embryonic and amniotic parts of the ectoderm, is of relatively slow growth and gradually forms a constriction between the embryo and the greater part of the archenteron. By means of this constriction, which corresponds to the future umbilicus, the dorsal part of the archenteron is enclosed within the embryo and constitutes the *primitive digestive tube*; the ventral part is left outside the embryo and constitutes the *yolk-sac*.

The embryo grows more rapidly in length than in width, and its cephalic and caudal ends bend in a ventral direction to form the *cephalic* and *caudal folds* respectively (figs. 89 and 90). The cephalic fold is first formed, and the forward growth of the head necessarily carries with it the posterior end of the pericardial area, so

that this area and the buccopharyngeal membrane are folded under the head of the embryo. A diverticulum of the archenteron, named the *fore-gut*, is enclosed in the cephalic fold. The caudal end of the embryo is connected to the chorion by a band of mesoderm called the *body-stalk*, but with the continued growth of this

FIG. 81.—Chick embryo of thirty-three hours' incubation, viewed from the dorsal aspect. $\times 30$. (From Duval's Atlas d'Embryologie.)

end and the formation of the caudal fold the body-stalk assumes a ventral position ; a diverticulum of the archenteron extends into the caudal fold and is termed the *hind-gut*. Between the fore-gut and the hind-gut there exists for a time a wide opening into the yolk-sac, but the relatively slow growth of the latter reduces it to a small pear-shaped sac (sometimes termed the *umbilical vesicle*), and the channel of communication is at the same time elongated to form a narrow tube called the *vitelline duct*.

THE YOLK-SAC

The **yolk-sac** (figs. 84 and 85) is situated on the ventral aspect of the embryo ; it is lined by entoderm, outside of which is a layer of mesoderm. It is filled with *vitelline fluid*, which is possibly utilised for the nourishment of the embryo during

FIG. 82.—Transverse section of a chick embryo of forty-five hours' incubation. (Balfour.)

the earlier stages of its existence. Blood is conveyed to the wall of the sac by the ventral branches of the primitive aortæ, and, after circulating through a wide-meshed capillary plexus, is returned by the vitelline veins to the tubular heart of the embryo. By means of this circulation nutritive material is absorbed from the yolk-sac and conveyed to the embryo. At the end of the fourth week the yolk-sac presents the

FIG. 83.—Dorsum of human embryo, 2.11 mm. in length. (After Ebernöl.)

appearance of a small pear-shaped vesicle (umbilical vesicle) opening into the digestive tube by a long narrow tube, the *vitelline duct*. The vitelline duct loses its attachment to the digestive tube, and as a rule undergoes complete obliteration during the seventh week, but in about two per cent. of cases its proximal part persists as a diverticulum (*Meckel's diverticulum*) from the small intestine, situated

about one metre above the ileocolic junction, and sometimes attached by a fibrous cord to the abdominal wall at the umbilicus. A narrowing of the lumen of the ileum is occasionally found opposite the site of attachment of the duct.

FIG. 84.—Section through the embryo which is represented in fig. 80.
(After Graf Spee.)

FIG. 85.—Human embryo of 2.6 mm. (His.)

The umbilical vesicle can be seen in the after-birth as a small somewhat oval-shaped body with a diameter of from 1 to 5 mm. : it is situated between the amnion and the chorion, and may lie on, or at a variable distance from, the placenta.

FŒTAL MEMBRANES AND THE PLACENTA

The allantois (figs. 84, 89, 90).—The allantois arises as a tubular diverticulum of the posterior part of the archenteron ; when the hind-gut is developed the allantois is carried backwards with it, and then opens from the cloaca or terminal part of

FIG. 86.—Fœtus of about eight weeks, enclosed in the amnion. Magnified a little over 2 diameters. Drawn from stereoscopic photographs lent by Prof. A. Thomson, Oxford.

the hind-gut : it extends into the mesoderm of the body-stalk which connects the tail end of the embryo with the chorion. The allantoic diverticulum is lined by entoderm and covered by mesoderm, and in the latter are umbilical vessels.*

* In reptiles, birds, and many mammals the allantois expands into a vesicle which projects into the extra-embryonic coelom. If its further development be traced in the bird, it is seen to project to the right side of the embryo, and, gradually expanding, spreads over the dorsal surface of the embryo as a flattened sac between the amnion and the serosa (p. 61*), and ultimately surrounds the yolk. Its outer wall becomes applied to, and fuses with, the serosa, which lies immediately inside the shell membrane. Blood is carried to the allantoic sac by the two allantoic or umbilical arteries, which are continuous with the primitive aortae, and after circulating through the allantoic capillaries, is returned to the primitive heart by the two umbilical veins. In this way the allantoic circulation, which is of the utmost importance in connexion with the respiration and nutrition of the chick, is established. Oxygen is taken from, and carbonic acid is given up to the atmosphere through the egg-shell, and nutritive materials are at the same time absorbed by the blood from the yolk. With the formation of the amnion the embryo is, in most animals, entirely separated from the chorion, and is only again united to the chorion when the allantoic mesoderm spreads over and becomes applied to its inner surface ; but the human embryo, as was pointed out by His, is never wholly separated from the chorion, its tail end being from the first connected with the chorion by means of a thick band of mesoderm, named the *body-stalk* (Bauchstiel).

FIG. 87.—Diagram showing earliest observed stage of human ovum.

FIG. 88.—Diagram illustrating early formation of allantois and differentiation of body-stalk.

FIG. 89.—Diagram showing later stage of allantoic development with commencing separation of the yolk-sac.

FIG. 90.—Diagram showing the expansion of amnion and delimitation of the umbilicus.

FIG. 91.—Diagram illustrating a later stage in the development of the umbilical cord.

The **amnion** is a membranous sac which surrounds and protects the embryo ; it is developed in reptiles, birds, and mammals, but not in amphibia and fishes.

In the human embryo the earliest stages of the formation of the amnion have not been observed ; in the youngest embryo which has been studied the amnion was

FIG. 92.—Transverse section of umbilical cord.

already present as a closed sac (figs. 87 and 94), and, as indicated on page 50, appears as a cavity in the ectodermal part of the inner cell-mass. This cavity is roofed in by a stratum of flattened ectodermal cells, the *amniotic ectoderm*, and its floor consists of the prismatic ectoderm of the embryonic disc—the continuity between the roof and floor being established at the margin of the embryonic disc.

FIG. 93.—Drawing of a model of a human embryo 1·3 mm. long. (After Eternod.)

Outside the amniotic ectoderm is a thin layer of mesoderm, continuous with that of the somatopleure and connected by means of the body-stalk with the mesodermal lining of the chorion.*

* In reptiles, birds, and many mammals the amnion is developed as follows:—At the constriction where the primitive digestive tube of the embryo joins the yolk-sac, a reflection or upfolding of the somatopleure takes place. This, the *amniotic fold*, first makes its appearance at the cephalic end, and subsequently at the caudal end and sides of the embryo, and gradually rising more and more its different parts meet and fuse over the dorsal surface of the embryo, and enclose a cavity, the *amniotic cavity*. After the fusion of the edges of the amniotic fold, the two layers of the fold separate; the inner forms the *amnion*, the outer, the *false amnion* or *serosa*. The space between the amnion and the serosa constitutes the extra-embryonic coelom, and for a time communicates with the embryonic coelom.

EMBRYOLOGY

Fluid, termed *liquor amnii*, appears within the amniotic cavity and increases steadily in amount, so that the sac gradually expands and encroaches on the cavity of the extra-embryonic coelom; this expansion continues until the extra-embryonic coelom is obliterated. The liquor amnii increases in quantity up to the sixth or seventh month of pregnancy, and then diminishes somewhat; at the end of pregnancy it amounts to about 1 litre. It allows of the free movements of the foetus during the later stages of pregnancy, and also protects it by diminishing the risk of injury from without. It contains less than two per cent. of solids, consisting of urea and other extractives, inorganic salts, a small amount of protein, and frequently a trace of sugar.

FIG. 91.—Section through an ovum imbedded in the uterine decidua. Semidiagrammatic. (After Peters.)

The body-stalk and umbilical cord.—The body-stalk (figs. 84, 89, 90, 93) is a band of mesoderm which from the first connects the tail end of the embryo with the chorion. Extending into the proximal part of it is the canal of the allantois, and running through it from the embryo to the chorion are the umbilical vessels. Its dorsal surface is covered by the amnion and its ventral surface is bounded by the extra-embryonic coelom. As a result of the folding of the embryo and the distension of the amnion the body-stalk comes to lie on the ventral surface of the embryo, and its mesoderm approaches that of the yolk-sac and vitelline duct (fig. 90). As a consequence of the continued expansion of the amnion the extra-embryonic coelom is obliterated (figs. 90, 91), the vitelline duct is elongated, and the mesoderm of the amnion blends with that of the vitelline duct and body-stalk; by this fusion a solid cord, the *umbilical cord*, is formed (fig. 91) and connects the embryo to that portion of the chorion which will form the foetal part of the placenta.

The umbilical cord (figs. 92, 100) is enveloped by the amniotic ectoderm and consists of a core of gelatinous tissue (jelly of Wharton) in which the umbilical vessels, the allantoic diverticulum, and the vitelline duct and vessels are imbedded.

The allantoic diverticulum and the vitelline duct and vessels undergo obliteration and atrophy, but traces of them may be seen up to the fourth month or later. The umbilical cord becomes spirally twisted, owing, it is believed, to the unequal growth

FIG. 95.—Primary chorionic villi. (Diagrammatic.) (Modified from Bryce.)

of the two umbilical arteries, it also increases in length so that at the end of pregnancy it averages about 50 cm

Implantation or imbedding of the fertilised ovum in the uterine wall.—As already stated (page 47), fertilisation of the ovum is believed to occur in the lateral or ampullary end of the uterine tube, and is immediately followed by segmentation. The segmenting ovum is conveyed along the uterine tube to the cavity of the uterus,

FIG. 96.—Secondary chorionic villi. (Diagrammatic.) (Modified from Bryce.)

the journey occupying seven or eight days. By the time it reaches the uterus it possesses a well-developed trophoblast. The ovum adheres like a parasite to the uterine mucous membrane, destroys the epithelium over the area of contact, and excavates for itself a cavity in the mucous membrane in which it becomes imbedded.

In an ovum described by Bryce and Teacher* the point of entrance of the ovum into the uterine mucous membrane was visible as a small gap closed by a mass of fibrin and leucocytes; in an ovum described by Peters† the opening was covered by a mushroom-shaped mass of fibrin and blood-clot (fig. 94), the narrow stalk of which plugged the aperture in the mucous membrane. Soon, however, all trace of the opening is lost, and the ovum is then completely surrounded by the uterine mucous membrane.

The structure actively concerned in excavating the uterine mucous membrane is the trophoblast. This increases rapidly in thickness, invades and digests the uterine tissues, destroys the epithelial cells of the uterine glands and the walls of the uterine (maternal) blood-vessels (fig. 94); at the same time there appear in the trophoblast numerous anastomosing spaces which are filled with maternal blood. These spaces expand to form what is ultimately known as the *intervillous space*, and the trophoblast is separated into a number of branching processes named the

FIG. 97.—Transverse section of a chorionic villus.

primary chorionic villi (fig. 95) which are bathed in the maternal blood. Cores of mesoderm, containing branches of the umbilical vessels, soon invade these primary villi and convert them into *secondary chorionic villi* (figs. 96, 97).

The decidua.—Before the fertilised ovum reaches the uterus, the mucous membrane of the body of the uterus undergoes important changes, and is then known as the *decidua*. The thickness and vascularity of the mucous membrane are greatly increased; its glands are elongated and open on its free surface by funnel-shaped orifices, while their deeper portions are tortuous and dilated into irregular spaces. The interglandular tissue is also increased in quantity, and is crowded with large round, oval, or polygonal cells, termed *decidual cells*. These changes are well advanced by the second month of pregnancy, when the mucous membrane consists of the following strata (fig. 98): (1) *stratum compactum*, next the free surface; in this the uterine glands are only slightly expanded, and are lined by columnar cells; (2) *stratum spongiosum*, where the uterine glands are greatly dilated and very tortuous, and are ultimately separated from one another by only a small amount of interglandular tissue; for a time the cells lining the glands are cylindrical, but later they become flattened; (3) a thin *limiting or boundary layer*, next the uterine muscular fibres, containing the deepest parts of the uterine glands, which are not dilated, and are lined with cubical epithelium; it is from this epithelium that the epithelial lining of the uterus is regenerated after pregnancy.

* Contribution to the study of the early development and imbedding of the human ovum, 1909.

† *Einbettung des menschlichen Eies*, 1899.

After the ovum is imbedded distinctive names are applied to different portions of the decidua. The part which covers in the ovum is named the *decidua capsularis*; the portion between the ovum and the uterine muscular wall is named the *decidua basalis* or *decidua placentalis*; it is here that the placenta is subsequently developed; the part which lines the remainder of the body of the uterus is known as the *decidua vera* or *decidua parietalis*.

Coincidentally with the growth of the embryo, the decidua capsularis is thinned and distended (fig. 99) and the space between it and the decidua vera is gradually obliterated. By the beginning of the third month of pregnancy the decidua capsularis and decidua vera are in contact; by the fifth month of pregnancy the decidua capsularis has practically disappeared, while during the succeeding months the decidua vera also undergoes atrophy, owing to the increased pressure. The glands of the stratum compactum are obliterated, and their epithelium is lost; in the stratum spongiosum the glands are compressed and appear as slit-like fissures, and their epithelium undergoes degeneration in the limiting or boundary layer; however, the glandular epithelium retains a cubical form.

The chorion (figs. 89 to 93 and 95 to 97).—The chorion consists of two layers: an outer of trophoblast, and an inner of mesoderm. The trophoblast consists of an internal layer, the *cytotrophoblast* or *layer of Langhans*, and an external layer, the *syncytiotrophoblast*. As stated (page 64) it undergoes rapid proliferation and forms, on the surface of the chorion, numerous processes, the *primary chorionic villi* (fig. 95); these increase in size and ramify, and the chorionic mesoderm, carrying branches of the umbilical vessels, grows into them, and in this way they are converted into *secondary chorionic villi* (fig. 96). Blood is carried from the embryo to the chorion by the umbilical arteries, and after circulating through the capillaries of the villi, is returned to the embryo by the umbilical veins. Until about the end of the second month of pregnancy the villi cover the entire chorion, are almost uniform in size, and project into the decidua placentalis and decidua capsularis (fig. 99). With the growth of the embryo and the expansion of the amniotic cavity the decidua capsularis is thinned and compressed, the circulation through it is gradually cut off, and the villi of the corresponding part of the chorion atrophy and disappear. This portion of the chorion becomes smooth (*chorion laeve*); and, as it takes no share in the formation of the placenta, is sometimes named the non-placental part of the chorion. On the other hand, the villi on that

FIG. 98.—Diagrammatic sections of the uterine mucous membrane; (A) of the non-pregnant uterus; (B) of the pregnant uterus, showing the thickened mucous membrane and the altered condition of the uterine glands. (Kundrat and Engelmann.)

part of the chorion which is in contact with the decidua placentalis increase greatly in size and complexity, and hence this part is named the *chorion frondosum* (figs. 90, 91).

The placenta (figs. 99 to 101).—The placenta connects the fetus to the uterine wall, and is the organ by means of which the nutritive, respiratory, and excretory functions of the fetus are carried on. It is composed of fetal and maternal parts.

The *fetal portion of the placenta* consists of the villi of the chorion frondosum which branch repeatedly, and increase enormously in size. The ends of some of them are anchored by columns of trophoblast to the walls of the intervillous space, but the majority hang free in this space. All are bathed in maternal blood, which is conveyed to and from the space by the uterine vessels. Blood is carried from the embryo to the placental villi by the umbilical arteries, and returned to the embryo by the umbilical veins. One or two branches of an artery enter each villus and there end in a capillary plexus which is drained by one or two tributaries of

FIG. 99.—Sectional plan of the gravid uterus in the third month.
(Modified from Wagner.)

the veins. The vessels of the villi are surrounded by a thin layer of mesoderm which is covered by the two strata of the trophoblast, the cytotrophoblast or layer of Langhans being in contact with the mesoderm, and the syncytiotrophoblast in contact with the maternal blood (fig. 101). After the fifth month the two strata of cells are replaced by a single layer of somewhat flattened cells.

The *maternal portion of the placenta* is formed by the decidua placentalis containing the intervillous space. As already explained, this space is produced by the enlargement and intercommunication of the spaces in the trophoblast; it is therefore lined throughout by syncytiotrophoblast. The formation of the intervillous space involves the disappearance of the greater portion of the stratum compactum, but the deeper part of this layer persists and is condensed to form what is known as the *basal plate*; this constitutes the outer wall of the intervillous space, and consists of a stroma containing decidual cells, portions of trophoblast and *fibrinoid substance*; the last appears to be derived in part from the trophoblast and in part from the maternal blood. Between the basal plate and the uterine muscular fibres are the stratum spongiosum and the limiting layer; through these and the basal plate the uterine arteries and veins pass to and from the intervillous space. Portions of the stratum compactum persist as pillars which project into the intervillous space, but these pillars do not extend as far as the chorion, except in the marginal part of the placenta; later they form the *placental septa* which incompletely divide the placenta into lobes or *cotyledons*.

Maternal blood is conveyed to the intervillous space by branches of the uterine arteries and carried away by tributaries of the uterine veins (figs. 100, 101). These vessels lose their muscular coats as they enter the basal plate, in which they consist of sinuous channels lined only by endothelium; these channels open into the intervillous space, the arteries ending near the placental septa and the veins beginning near the centres of the cotyledons. The endothelial lining of the uterine vessels ends where the vessels open into the intervillous space which is lined throughout by syncytiotrophoblast. The circumferential part of the intervillous space consists of an irregular channel named the *marginal sinus* (fig. 101); this sinus partly encircles the placenta and communicates peripherally with the uterine veins, and centrally with the intervillous space; clusters of placental villi project into it.

FIG. 100.—Fœtus in utero, between fifth and sixth months.

The foetal and maternal blood-currents do not intermingle, being separated from each other by the delicate walls of the villi. Nevertheless, the foetal blood is able to absorb, through the walls of the villi, oxygen and nutritive materials from the maternal blood, and give up to the latter its waste products. The blood, so purified, is carried back to the foetus by the umbilical vein. It will thus be seen that the placenta not only establishes a mechanical connexion between the mother and the foetus, but subserves for the latter the purposes of nutrition, respiration, and excretion. In favour of the view that the placenta possesses certain selective powers may be mentioned the fact that glucose is more plentiful in the maternal than in the foetal blood. It is interesting to note also that the proportion of iron and of lime and potash in the foetus is increased during the last months of pregnancy. Further, there is evidence that the maternal leucocytes may migrate into the foetal blood, since leucocytes are much more numerous in the blood of the umbilical vein than in that of the umbilical arteries.

The placenta is usually attached near the fundus uteri, and its site corresponds with that at which the ovum is imbedded. It may, however, occupy a lower level,

and in very rare cases occludes the internal orifice of the uterus, thus giving rise to the condition known as *placenta prævia*.

Separation of the placenta.—After the child is born, the placenta and membranes (the latter consisting of the amnion, the chorion lœve and the superficial part of the decidua parietalis) are separated from the uterine wall and expelled as the *after-birth*. The separation takes place along the plane of the stratum spongiosum (fig. 101), and necessarily causes rupture of the uterine vessels. The orifices of the torn vessels are, however, closed by the firm contraction of the uterine muscular fibres, and thus *post-partum hæmorrhage* is prevented. After the separation of the placenta and membranes a thin layer of the stratum spongiosum is left as a lining to the uterus, but this layer subsequently undergoes degeneration, and is cast off. The mucous membrane, the glands and the epithelial lining of the uterus are regenerated from the limiting or boundary layer of the decidua (page 64).

The expelled placenta is a discoid mass which has a weight about 500 gm., a diameter of from 15 cm. to 20 cm., and an average thickness of about 3 cm., but

FIG. 101.—Scheme of placental circulation.

the thickness rapidly diminishes near the circumference of the disc, which is continuous with the membranes. Its uterine or outer surface is divided by a series of fissures into lobules or *cotyledons* which are imperfectly separated from one another by the placental septa. Its foetal or inner surface is smooth, and is closely invested by the amnion. Seen through the latter, the chorion presents a mottled appearance, consisting of grey, purple, or yellowish areas. The umbilical cord is usually attached near the centre of the placenta, but may be inserted anywhere between the centre and the margin; in some cases it is inserted into the membranes, i.e. the *velamentous* insertion. From the site of the attachment of the cord the larger branches of the umbilical vessels radiate under the amnion, the veins being deeper and larger than the arteries. The remains of the vitelline duct and yolk-sac may be sometimes observed beneath the amnion, close to the cord, the former as an attenuated thread, the latter as a minute sac.

On section, the placenta presents a soft, spongy appearance, caused by the greatly branched villi; surrounding them is a varying amount of maternal blood, giving the dark red colour to the placenta.

The further growth of the embryo will be best understood from a description of the principal facts relating to the development of the chief systems of which the body consists.

DEVELOPMENT OF THE PARIETES

The skeleton.—The skeleton is of mesodermal origin, and may be divided into (1) the axial skeleton, viz. that of the vertebral column, skull, ribs, and sternum, and (2) the appendicular skeleton, viz. that of the limbs.

The vertebral column.—The notochord (fig. 82) is a temporary structure and forms a central axis, around which the segments of the vertebral column are developed.* It is derived from the anterior end of the primitive streak, and, when fully formed, consists of a rod of cells, which lies on the ventral aspect of the neural tube and reaches from the anterior end of the mid-brain to the extremity of the tail. On either side of it is a column of paraxial mesoderm which becomes subdivided into a number of

more or less cubical segments, the *primitive segments* (figs. 81 and 83). These are separated from one another by *intersegmental septa* and are arranged symmetrically on either side of the neural tube and notochord: to every segment a spinal nerve is distributed. At first each segment contains a central cavity, the *myocœl*, but this is soon filled with a core of angular and spindle-shaped cells. The cells of the segment are differentiated into three groups, which form respectively the *cutis-plate* or *dermatome*, the *muscle-plate* or *myotome*, and the *sclerotome* (fig. 102). The *cutis-plate* is placed on the lateral and dorsal aspect of the *myocœl*, and from it the true skin of the corresponding segment is derived; the *muscle-plate* is situated on the medial side of the *cutis-plate*, and furnishes

FIG. 102.—Transverse section of a human embryo of the third week, to show the differentiation of the primitive segment. (Kollmann.)

ao, aorta; m.p., muscle-plate; n.c., neural canal; sc., sclerotome; s.p., cutis-plate.

the muscles of the segment. The cells of the *sclerotome* are largely derived from those forming the core of the *myocœl*, and lie next the notochord. Fusion of the individual *sclerotomes* in an anteroposterior direction soon takes place, and thus a continuous strand of cells, the *scleratogenous layer*, is formed along the ventrolateral aspects of the neural tube. The cells of this layer proliferate rapidly, and extending medialwards surround the notochord; at the same time they grow backwards on the lateral aspects of the neural tube and eventually surround it, and thus the notochord and neural tube are enveloped by a continuous sheath of mesoderm (fig. 104), which is termed the *membranous vertebral column*. In this mesoderm the original *sclerotomes* are still distinguishable, but each is now differentiated into two portions, an anterior, consisting of loosely arranged cells, and a posterior, of more condensed tissue (fig. 103, A and B). Between the two portions the rudiment* of the intervertebral fibrocartilage is laid down (fig. 103, C). Cells from the posterior mass grow into the intervals between the *myotomes* (fig. 103, B and C) of the corresponding and succeeding segments, and extend both dorsally

* In *Amphioxus* the notochord persists and is the only representative of a skeleton in that animal.

and ventrally; the dorsal extensions surround the neural tube and represent the future vertebral arch, while the ventral extend into the body-wall as the costal processes. The hinder part of the posterior mass joins the anterior mass of the succeeding sclerotome to form the vertebral body. Each vertebral body is therefore

FIG. 103.—Scheme showing the manner in which each vertebral body is developed from portions of two adjacent segments.

a composite of two segments, being formed from the posterior portion of one and the anterior part of that immediately behind it. The vertebral and costal arches are derivatives of the posterior part of the segment in front of the intersegmental septum with which they are associated.

This stage is succeeded by that of the *cartilaginous vertebral column*. In the fourth week cartilaginous centres make their appearance on either side of the notochord; these extend round the notochord and form the bodies of the cartilaginous vertebrae. A pair of cartilaginous foci appear in the lateral parts of each vertebral arch, and grow backwards on either side of the neural tube to form the cartilaginous vertebral arch, and a separate cartilaginous centre appears for each costal process. In the eighth week the cartilaginous vertebral arch fuses with

FIG. 104.—Diagram showing (A) membranous and (B) cartilaginous stages of a typical vertebra.

the cartilaginous body, and in the fourth month the halves of the arch unite on the dorsal aspect of the neural tube (fig. 104, B); the spinous process is developed from the junction of the halves of the vertebral arch. The transverse processes grow out from the vertebral arch behind the costal processes.

In the upper cervical vertebrae a band of mesodermal tissue connects the lateral extremities of the vertebral arches across the ventral surfaces of the intervertebral

fibrocartilages. This is termed the *hypochordal bar* or *brace* (fig. 105, A); in all except the atlas or first cervical vertebra it is transitory and fuses with the fibrocartilages. In the atlas, however, it persists, undergoes chondrification, and develops into the anterior arch of this bone, while the cartilage representing the body

FIG. 105.—Diagrams showing transformation of hypochordal bar into anterior arch of atlas.

of the atlas forms the dens or odontoid process which fuses with the body of the second cervical vertebra (fig. 105, B).

The portions of the notochord contained within the bodies of the vertebrae atrophy, and ultimately disappear, while those which lie in the centres of the intervertebral fibrocartilages expand, and persist throughout life as the central *nucleus pulposus* of the fibrocartilages (fig. 106).

The ribs.—The ribs are formed from the costal processes of the primitive vertebral arches, the processes extending between the muscle-plates. In the *thoracic region* of the vertebral column the costal processes grow lateralwards to form a series of arches, the *primitive costal arches*. The transverse process grows out behind the vertebral end of the costal process, and is at first connected to this process by mesoderm which is later differentiated to form the costotransverse ligaments; between the costal process and the tip of the transverse process the costotransverse

FIG. 106.—Sagittal section through an intervertebral fibrocartilage and adjacent parts of two vertebrae of a sheep's embryo. (Kölliker.)

joint is formed by absorption, while the proximal end of the costal process becomes separated from the vertebral arch by the development of the costocentral joint. In the *cervical vertebrae* (fig. 107) the transverse process forms the posterior boundary of the foramen transversarium, while the costal process, corresponding to the head and neck of the rib, remains in continuity with the body of the vertebra, and forms the anterolateral boundary of this foramen. The distal portions of the primitive

costal arches remain undeveloped ; occasionally, however, the costal processes of the seventh cervical vertebra undergo greater development, and by the formation of costovertebral joints are separated off as ribs. In the *lumbar region* the distal portions of the primitive costal arches fail ; the proximal portions fuse with the transverse processes to form the transverse processes of descriptive anatomy. Occasionally a movable rib is developed in connexion with the first lumbar vertebra. In the *sacral region* costal processes are developed only in connexion with the upper

FIG. 107.—Diagrams showing the portions of the adult vertebra derived respectively from the bodies, vertebral arches, and costal processes of the embryonic vertebrae.

The bodies are represented in yellow, the vertebral arches in red, and the costal processes in blue.

three or four vertebrae ; the processes of adjacent segments fuse with one another to form the lateral parts of the sacrum. The *coccygeal vertebrae* are devoid of costal processes.

The sternum.—The ventral ends of the ribs become united to one another by a longitudinal bar termed the *sternal plate*, and opposite the first seven pairs of ribs these sternal plates fuse in the middle line to form the manubrium and body of the sternum. The xiphoid process is formed by a backward extension of the sternal plates.

The skull.—The bones of the cranium are developed from the mesoderm which invests the cerebral vesicles. At the end of the first and beginning of the second month of foetal life this mesoderm begins to thicken and form masses of blastema. These blastemal masses represent the earliest distinguishable elements of the skeleton of the head, and first become evident in the occipital region where they

form a plate, the so-called *occipital plate*; in the middle of this plate the notochord runs sagittally. The occipital plate sends out on either side two processes which surround the hypoglossal nerve and form the hypoglossal canal.

The occipital plate is continued forwards as a thin blastemal layer on the dorsal aspect of the pharynx and reaches the rudiment of the hypophysis. At the beginning of the second month it surrounds the duct of the hypophysis and extends between the nasal fossæ where it forms the basis of the ethmoid and the nasal septum.

About the fifth week the two auditory vesicles become enclosed in blastemal capsules, each of which is soon differentiated into a dorsolateral part enveloping the semicircular canals and a ventromedial part surrounding the cochlea; at the upper boundary between these two parts the facial nerve lies in a deep groove. The blastemal auditory capsules fuse with the lateral processes of the occipital plate, leaving, however, a wide gap between each capsule and the more median part of the occipital plate; through this gap the internal jugular vein, and the glossopharyngeal, vagus and accessory cerebral nerves are transmitted.

At this stage the blastema which surrounds the hypophysial duct and forms the rudiment of the post-sphenoidal part of the body of the sphenoidal bone, sends

FIG. 108.—Sagittal section of the cephalic end of the notochord. (Keibel.)

FIG. 109.—Diagrams of the cartilaginous cranium. (Wiedersheim.)

out a wing-like process on either side, the future great wing (*ala magna*) of the sphenoidal bone. More anteriorly, from the central blastema which is to form the interorbitonasal septum, processes extend laterally and indicate the sites of the small wings (*alæ parvæ*) of the sphenoidal bone, while condensations occur on either side of the nasal fossæ and blend above with the blastemal septum.

The first indications of the vault of the skull are seen about the thirtieth day, and consist of blastemal plates which appear at the sides of the head and gradually extend into the upper wall where they blend with one another; they also blend with the blastema at the base of the cranium.

In the shark and dogfish this blastemal cranium undergoes complete chondrification and forms the cartilaginous skull or chondrocranium of these animals. In mammals the process of chondrification is limited to the base of the skull, including a narrow region dorsal to the foramen magnum. Chondrification takes place primarily in two regions: (a) the posterior or *chordal* part of the base of the skull is developed from the blastema which surrounds the notochord, and exhibits traces of four primitive segments separated from one another by the roots of the hypo-

FIG. 110.—Drawing of a model of the chondrocranium of a human embryo 8 cm. long.
(From Hertwig's *Handbuch der Entwicklungslehre*.)

glossal nerve; (b) the anterior or *prechordal* part is developed in front of the notochord and shows no regular division into primitive segments.

In the lower animals a pair of cartilages appears in each part, viz. a pair of *parachordal cartilages*, one on either side of the notochord, and a pair of *prechordal cartilages* or *trabeculae cranii*, in front of the notochord (fig. 109). These structures are represented in man by paired nuclei of chondrification in the chordal and prechordal parts respectively.

* Chondrification of the skull begins in the second month of foetal life, even

* The following description is mainly based on the extensive researches of E. Fawcett. The reader is referred for further details to the *Journal of Anatomy and Physiology*, volumes xlv. and xlvi., and to the *Proceedings of the Anatomical Society of Great Britain and Ireland* for the year 1918.

before the blastemal stage is completed, and the first nuclei appear in the occipital plate, one on either side of the notochord, medial to the hypoglossal canal. About the thirty-sixth day these two nuclei fuse anteriorly on the dorsal surface of the notochord, and later they fuse posteriorly on its ventral surface. Thus the notochord lies dorsal to the caudal part of the cartilaginous occipital plate, then traverses the plate and lies ventral to it, and finally passes in front of it and ends on the dorsal surface of the post-sphenoidal cartilage (fig. 108).

The posterior part of the sphenoidal cartilage chondrifies from two centres (*trabeculae cranii*) one on either side of the developing hypophysis; these unite first behind and then in front of the duct of the hypophysis, and in this way the craniopharyngeal canal, through which the hypophyseal diverticulum ascends into the skull, is formed; this canal is usually obliterated at the third month, but may remain open.

The central blastema, in front of the hypophysis probably undergoes independent chondrification; it speedily joins with the posterior end of the chondrifying inter-

FIG. 111.—The same model as shown in fig. 110, from the left side.

Certain of the membrane-bones are represented in yellow.

orbitonasal septum, and from these are subsequently developed the presphenoidal part of the sphenoidal bone and the bony (ethmoidal) part of the nasal septum. All the above-mentioned parts ultimately fuse and form a continuous cartilaginous stem from the anterior edge of the foramen magnum to the anterior end of the nose.

The blastemal auditory capsule next undergoes chondrification, the portion surrounding the semicircular canals chondrifying before that enveloping the cochlea. From the cartilaginous occipital plate, lateral to the hypoglossal canal, a cartilaginous bar extends on either side; these two bars pass partly under the canalicular part of the capsule, then dorsally over the brain, and ultimately meet in the mid-dorsal line to form the *tectum posterius*, which is afterwards ossified to form the lower part of the squama occipitalis. In front of this a narrow strip of cartilage, the *tectum anterius*, is developed, but later disappears.

The great wings of the sphenoidal bone have separate cartilaginous nuclei; these fuse with the post-sphenoidal cartilage and with two nuclei which connect the post-sphenoidal cartilage and the corresponding great wing with the anterior end of the cochlear capsule, lateral to the carotid artery. These nuclei form, on either side, the alar process which later ossifies as the lingula. The cartilaginous great wing is smaller than the small wing and only gives rise to the root of the pterygoid process and to that part of the bone which surrounds the maxillary division of the trigeminal nerve.

Between the great wing and the auditory capsule is a wide space which lodges the semilunar (Gasserian) ganglion and transmits the mandibular division of the trigeminal nerve and the middle meningeal artery. The backward growth of the alar process cuts off this space from the carotid canal, and at a later date the mandibular nerve and middle meningeal artery are surrounded by membrane bone. The space between the great and small wings forms the superior orbital (sphenoidal) fissure.

Chondrification of the small wing commences lateral to the optic nerve, and from this centre ingrowths extend in front of and behind the optic nerve and fuse with hinder part of the interorbitonasal septum and so form the optic foramen. Ossification of the small wing begins just lateral to the optic foramen, but does not extend very far out; a considerable part of the cartilage disappears, and owing to this, the small wing, in the bony condition, is much smaller than the great wing.

The nasal capsule is situated in front of the small wings, and is well developed by the third month; it consists of a central part, or septum, and two lateral parts.

FIG. 112.—Ventral view of left half of nasal capsule of a 65 mm. human embryo. (Fawcett.)

The septum lies partly under the brain (subcerebral) and partly in front of the brain (precerebral); its lower margin is almost horizontal and is, for a time, free; its anterior border intervenes between the anterior nares (fenestræ narinae).

The lateral parts of the capsule are primarily suspended from the precerebral part of the septum; later they are connected with the subcerebral part of the septum by the lamina cribrosa of the ethmoidal bone. Each lateral part consists of an anterior, an intermediate and a posterior portion. The anterior and intermediate portions are separated externally by an anterolateral sulcus which corresponds internally with a semilunar crest; the lower end of this crest forms the uncinat process of the ethmoidal bone. The posterior and intermediate portions are separated by a faint postero-lateral sulcus which corresponds internally with the middle nasal concha. The lower edge of the lateral wall of the capsule is incurved to form the inferior nasal concha which, at the fifth month, becomes ossified and detached from the lateral wall of the capsule.

In man the floor of the nasal capsule is very incomplete. In rodents and some marsupials it consists of an anterior and a posterior transverse lamina connecting the lateral wall of the capsule with the septum; in front of the anterior lamina is the fenestra narina. The anterior and posterior transverse laminae are connected by a bar of cartilage which runs backwards alongside the septum and forms the common paranasal cartilage; the anterior part of this cartilage is bilaminar, and between the laminae the organ of Jacobson is lodged; the posterior part is small and cylindrical.

In man the greater part of the anterior transverse lamina has disappeared and thus the fenestra narina is continuous with the fenestra basalis, the two forming the fissura rostroventralis; the medial segment only of the anterior transverse lamina remains as the processus lateralis ventralis. Further, only the anterior and posterior segments of the common paraseptal cartilage are developed in man; these parts are termed the anterior and posterior paraseptal cartilages and are united to one another by fibrous membrane.

Part of the cartilaginous capsule is ossified to form the ethmoidal bone and the inferior nasal concha, part remains cartilaginous as the septal and alar cartilages of the nose, and part is replaced by membrane bones.

The ventral surface of the chondrocranium is indirectly connected with the cartilages of the visceral arches, the fate of which is described below.

The bones of the vault of the skull are of membranous formation, and are termed *dermal* or *covering bones*. They comprise the upper part of the squama occipitalis (interparietal), the squamæ and tympanic parts of the temporals, the parietals, the frontal. Some of them remain distinct throughout life (e.g. parietal and frontal), while others join with the bones of the chondrocranium (e.g. interparietal and squamæ of temporals).

The branchial or visceral arches and pharyngeal pouches.—In the lateral walls of the anterior part of the fore-gut five *pharyngeal pouches* appear (fig. 115); each of the upper four pouches is prolonged into a dorsal and a ventral diverticulum. Over these pouches corresponding indentations of the ectoderm occur, forming what are known as the *branchial* or *outer pharyngeal grooves*. The mesoderm which intervenes between the pharyngeal pouches and the outer pharyngeal grooves is pressed aside and the ectoderm unites with the entoderm of the fore-gut along the floors of the grooves to form thin *closing membranes* between the fore-gut and the exterior. Later the mesoderm again penetrates between the entoderm and the ectoderm. In gill-bearing animals the closing membranes disappear, and the grooves become the gill-clefts which open from the pharynx on to the exterior; perforation, however, does not occur in birds or mammals.

The pharyngeal grooves separate a series of rounded bars or arches, the *branchial* or *visceral arches* in which thickening and consolidation of the mesoderm take place (figs. 113 to 115). The dorsal ends of these arches are attached to the sides of the head, while the ventral extremities ultimately meet in the middle line of the neck. In all, six arches make their appearance, but of these only the first four are visible externally. The first arch is named the *mandibular*, and the second the *hyoid*; the others have no distinctive names. In each arch the central part of the mesoderm consolidates and is then converted into a cartilaginous bar, consisting of right and left halves. Moreover, each arch is traversed by a nerve and by one of the primitive aortic arches.

The *mandibular arch* lies between the stomodæum or primitive mouth and the first branchial-groove: from it are developed the lower lip, the mandible, the muscles of mastication, and the anterior part of the tongue. Its cartilaginous bar is formed by what are known as *Meckel's cartilages* (right and left) (fig. 116). The dorsal ends of these cartilages are ossified to form two of the three bones of the middle ear, viz. the malleus and incus; the ventral ends meet each other in the region of the

FIG. 113.—Embryo between eighteen and twenty-one days. (Hiss.)

symphysis menti, and are usually regarded as undergoing ossification to form that portion of the mandible which contains the incisor teeth. The intervening part of the cartilage disappears; the portion immediately adjacent to the malleus and incus is replaced by fibrous membrane which constitutes the sphenomandibular ligament, while from the connective tissue covering the remainder of the cartilage

FIG. 114.—Head end of a human embryo, about the end of the fourth week. (From model by Peter.)

the greater part of the mandible is ossified. From the dorsal ends of the mandibular arch a triangular process, the *maxillary process*, grows forwards on either side and forms the cheek and lateral part of the upper lip.

The second or *hyoid arch* assists in forming the side and front of the neck. From its dorsal median portion the third bone of the middle ear, viz. the stapes, is developed, and subsequently becomes attached to the auditory capsule. From the ventral part of the arch the styloid process, stylohyoid ligament, and lesser cornu of the hyoid bone are developed: the glossopalatine arch indicates the position of the hyoid arch. The cartilage of the *third arch* gives origin to the greater cornu of the hyoid bone. The ventral ends of the second and third arches unite with those of the opposite side, and form a transverse band, from which the body of the hyoid bone and the posterior part of the tongue are developed. The

ventral portions of the cartilages of the *fourth* and *fifth* arches unite to form the thyroid cartilage; from the cartilages of the *sixth arch* the cricoid and arytenoid cartilages and the cartilages of the trachea are developed.*

The mandibular and hyoid arches grow more rapidly than those behind them, with the result that the third and fourth arches recede from the surface and form the floor of a deep depression, the *sinus cervicalis*. The hyoid arch grows backwards and overlaps the sinus, the opening from which assumes the form of a narrow duct; this duct closes and converts the sinus into a vesicle which disappears at an early period of development.

From the first branchial groove the concha and the external acoustic meatus are developed, while around the groove there appear, on the mandibular and hyoid arches, a number of swellings from which the auricula or pinna is formed. From the upper or dorsal parts of the first and second pharyngeal pouches the auditory tube and the tympanic cavity are developed (page 107; the closing membrane between the mandibular and hyoid arches is invaded by mesoderm, and forms the tympanic membrane. No traces of the second, third, or fourth branchial grooves persist. The dorsal

angle of the second pharyngeal pouch is named the *sinus tonsillaris*; in it the tonsil is developed, and above the tonsil a trace of the sinus persists as the suprtonsillar

FIG. 115.—Floor of pharynx of embryo shown in fig. 114.

* Fawcett (*Proceedings of the Anatomical Society of Great Britain and Ireland*, 1916) is of opinion that the thyroid cartilage is formed from the fourth arch, and the cricoid cartilage from the fifth arch.

fossa. The lateral recess of the pharynx, or fossa of Rosenmüller, is by some regarded as a persistent part of the second pharyngeal pouch, but it is probably developed as a secondary formation. From the third pharyngeal pouch the thymus arises as an entodermal diverticulum on either side, and from the fourth pouches

FIG. 116.—Head and neck of a human embryo eighteen weeks old, with Meckel's cartilage and hyoid bar exposed. (After Kölliker.)

small diverticula project and become incorporated with the thymus, but in man they probably never form true thymus tissue. The parathyroids arise as diverticula from the third and fourth pouches. From the fifth pouches the ultimobranchial bodies originate and are enveloped by the lateral prolongations of the median thyroid rudiment; they do not, however, form true thyroid tissue, nor are any traces of them found in the human adult.

The nose and face.—During the third week two areas of thickened ectoderm, the *olfactory areas*, appear immediately under the fore-brain in the anterior wall of

FIG. 117.—Under surface of the head of a human embryo about twenty-nine days old. (After His.)

the stomodæum, one on either side of a region termed the *frontonasal process*. By the upgrowth of the surrounding parts these areas are converted into the *olfactory pits*, which indent the frontonasal process and divide it into a *medial* and two *lateral nasal processes* (figs. 117, 118). The rounded lateral angles of the medial

process are named the *globular processes* (His). The olfactory pits form the rudiments of the nasal cavities, and from their ectodermal lining the epithelium of the nasal cavities is derived, with the exception of that of the inferior meatuses which are formed from the stomodæum. The mesodermal plates represented on the surface by the globular processes are termed the *nasal laminæ*; these laminæ are at first some distance apart, but, gradually approaching, they ultimately fuse and form the nasal septum; the processes themselves meet in the middle line, and form the premaxillæ and the central part of the upper lip (fig. 121). The depressed part of the medial nasal process between the globular processes forms the lower part of the nasal septum or *columella*; while above this is seen a prominent angle, which becomes the future apex (fig. 118), and still higher a flat area, the future bridge of the nose. The lateral nasal processes form the alæ of the nose.

Continuous with the dorsal end of the mandibular arch, and growing forwards from its cephalic border, is a triangular process—the *maxillary process*—the ventral extremity of which is separated from the mandibular arch by a >-shaped notch

FIG. 118.—Head-end of a human embryo of about thirty to thirty-one days. (From model by Peter.)

FIG. 119.—Same embryo as shown in fig. 118, with the front wall of the pharynx removed.

(fig. 117). The maxillary process forms the lateral wall and floor of the orbit, and in it are ossified the zygomatic and palatine bones and the greater part of the maxilla; it meets with the lateral nasal process, from which, however, it is separated for a time by a groove, the *naso-optic furrow*, extending from the furrow encircling the eyeball to the olfactory pit. The maxillary processes ultimately fuse with the lateral nasal and globular processes, and form the lateral parts of the upper lip and the posterior boundaries of the nares (figs. 120, 121). From the third to the fifth month the nares are filled by masses of epithelium, on the breaking down and disappearance of which the permanent openings are produced. By the fusion of the maxillary processes with the nasal and globular processes in the roof of the stomodæum the *primitive palate* (fig. 122) is formed, and the olfactory pits extend backwards above it. The posterior end of each pit is closed by an epithelial membrane, the *bucco-nasal membrane*, formed by the apposition of the nasal and stomodæal epithelium. About the fifth week the bucconasal membranes rupture and the *primitive choanæ* or openings between the olfactory pits and the stomodæum are established. The floor of the nasal cavity is completed by the development of a pair of shelf-like *palatine processes* which appear about the sixth week and extend medialwards from the maxillary processes (figs. 123, 124); these coalesce with each other and with the nasal septum in the middle line, and constitute the entire hard plate, except a small part in front which is formed by the premaxillæ (page 229). The soft palate is

formed by two secondary backward growths, one on either side, from the palatine processes; into these the palatine muscles extend, and the two parts ultimately join to form the soft palate and uvula. Two apertures persist for a time between the palatine processes and the premaxillæ, and represent the permanent channels

FIG. 120.—Head of a human embryo of about eight weeks, in which the nose and mouth are formed. (His.)

FIG. 121.—Diagram showing the regions of the adult face and neck related to the frontonasal and maxillary processes and the branchial arches.

which in the lower animals connect the nose and mouth. The union of the parts which form the palate commences in front, the premaxillary and palatine processes joining in the eighth week, while the region of the future hard palate is completed by the ninth, and that of the soft palate by the eleventh week. By the completion of the palate the *permanent choanæ* are formed and are situated a considerable distance behind the primitive choanæ. The deformity known as cleft palate results from a non-union of the palatine processes, and that of hare-lip from a non-union of the maxillary and globular processes (see page 264). The nasal cavity is divided

FIG. 122.—Primitive palate of a human embryo of thirty-seven to thirty-eight days. (From model by Peter.)

On the left side the lateral wall of the nasal cavity has been removed.

by a cartilaginous septum, the anterior part of which persists as the septal cartilage of the nose, but the posterior and upper parts are replaced by the vomer and lamina perpendicularis of the ethmoid. On either side of the nasal septum, at its lower and anterior part, the ectoderm is invaginated to form a blind pouch or diverticulum which extends backwards and upwards into the nasal septum and is supported by

a curved plate of cartilage. These pouches form the rudiments of the *vomer* and *nasal organs* of Jacobson, which open below, close to the junction of the premaxillary and maxillary bones.*

FIG. 123.—The roof of the mouth of a human embryo about two and a half months old, showing the mode of formation of the palate. (His.)

FIG. 124.—Frontal section of nasal cavities of a human embryo 28 mm. long. (Kollmann.)

The limbs.—In the third week the limbs begin to make their appearance as small elevations or buds at the side of the trunk (fig. 125). Prolongations from several primitive segments extend into each bud, and carry with them the anterior divisions of the corresponding spinal nerves; the nerves supplying the limbs indicate the number of primitive segments which contribute to their formation—the upper limb being derived from seven, viz. fourth cervical to second thoracic inclusive,

* J. Ernest Frazer (Hunterian Lecture, *Lancet*, July 8, 1916) maintains that the increase in size of the nasal cavities takes place in an upward and backward direction, and the septum is simply the part of the roof left undisturbed between the paired upgrowths. He also points out that by the ninth week the primitive choanae extend from the primitive palate to the top of the cavity of the mouth, and when the palatal folds meet they fuse with the lower two-thirds or three-fourths of the septum, while the upper one-fourth or so of the septum remains between the upper parts of the openings which constitute the permanent choanae.

and the lower limb from ten, viz. twelfth thoracic to fourth sacral inclusive. The axial part of the mesoderm of the limb-bud condenses and is converted into its cartilaginous skeleton, and by the ossification of this the bones of the limbs are formed. The limbs are at first directed backwards nearly parallel to the long axis of the trunk; by the sixth week their long axes are at right angles to that of the trunk, and the three chief divisions of each limb are marked off by furrows—arm, forearm, and hand in the upper limb; thigh, leg, and foot in the lower (fig. 126). The future *flexor* surface of the limb is directed ventrally; the *extensor* surface, dorsally; one border, the *pre-axial*, looks towards the cephalic end of the embryo, and the other, the *post-axial*, towards the caudal end. The lateral epicondyle of the humerus, the radius, and the thumb lie along the pre-axial border of the upper limb; the medial epicondyle of the femur, the tibia, and the great toe along the corresponding border of the lower limb. The limbs next undergo a rotation or torsion through an angle of 90° around their long axes, the rotation being effected almost entirely at the limb girdles. The rotation of the upper limb is outwards and forwards; that of the lower limb is inwards and backwards. As a consequence of this rotation the pre-axial (radial) border of the fore-limb is directed lateralwards, and the pre-axial (tibial) border of the hind-limb medialwards; thus the flexor surface of the fore-limb is turned forwards, and that of the hind-limb backwards.

FIG. 126.—Embryo of about six weeks. (Hiss.)

FIG. 125.—Human embryo from thirty-one to thirty-four days. (Hiss.)

The pre-axial part is derived from the anterior primitive segments, the post-axial from the posterior primitive segments of the limb-bud; and this explains, to a large extent, the innervation of the adult limb, the nerves of the more anterior segments being distributed along the pre-axial (radial or tibial), and those of the more posterior segments along the post-axial (ulnar or fibular) border of the limb.

The joints.—The mesoderm from which the different parts of the skeleton are formed at first shows no differentiation into masses corresponding with the individual bones; thus, continuous cores of mesoderm form the axes of the limb-buds and a continuous column of mesoderm the future vertebral column. The first indications of the differentiation of the bones and

joints are circumscribed condensations of the mesoderm; these condensed parts become chondrified and finally ossified to form the bones of the skeleton. The intervening non-condensed portions consist at first of undifferentiated mesoderm, which may be converted into fibrous tissue as in the case of the skull bones, a synarthrodial joint being the result; or it may become partly cartilaginous, in which case an amphiarthrodial joint is formed; or it may become

looser in texture, a cavity ultimately appearing in its midst, while the cells lining the sides of this cavity form a synovial stratum, and thus a diarthrodial joint is developed; in some diarthrodial joints portions of the mesoderm persist and form articular discs.

The tissue surrounding the original mesodermal core forms fibrous sheaths for the developing bones (perichondrium and periosteum) which are continued between the ends of the bones over the synovial strata as the fibrous capsules of the joints. These capsules are not of uniform thickness, so that in them may be recognised specially strengthened bands which are described as ligaments. This, however, is not the only method of formation of ligaments. In some cases by modification of, or derivations from, the tendons surrounding the joint, additional ligamentous bands are provided to strengthen the articulations.

The muscles.—The voluntary muscles are developed from the myotomes of the primitive segments. Portions of the myotomes retain their position on the sides of the neural tube, where they may remain distinct from each other and form the short muscles of the vertebral column, or fuse with corresponding portions of neighbouring myotomes to form the Sacrospinales and their continuations. Other portions of the myotomes extend into the trunk wall where again they may retain their segmental condition, as in the Intercostales, or may fuse with adjacent segments to form the flat muscles of the abdominal wall. Finally, portions of the myotomes wander into the limb-buds and there undergo fusions and alterations in form to produce the limb muscles. The original segmental character of the limb muscles is therefore lost, but their segmental nerve supplies are retained. Some of the limb muscles expand and migrate secondarily towards the mid-dorsal line (e.g. Trapezius and Latissimus dorsi) or towards the mid-ventral line (e.g. Pectoralis major). Again, muscles may migrate in a cephalic direction (e.g. the facial muscles which are derived from the hyoid arch), or in a caudal direction (e.g. the Serratus anterior). In all cases they carry with them the segmental nerves of the myotomes from which they are derived; one example of this will suffice, viz. the Serratus anterior, which is derived from the fifth, sixth, and seventh cervical segments as is indicated by its nerves of supply. In man and the higher vertebrates many of the derivatives of the myotomes degenerate and are converted into aponeuroses (e.g. galea aponeurotica, and the aponeuroses of the abdominal muscles) or ligaments (e.g. the sacrotuberous ligament and the fibular collateral ligament of the knee).

The involuntary muscles are derived from the splanchnopleure mesoderm.

The skin and its appendages.—The epidermis, hairs, nails, sebaceous and sudoriferous glands are developed from the ectoderm, the corium or true skin from the mesoderm. The ectoderm at first consists of a single stratum of cells, but by the fifth week two strata can be recognised, a superficial, named the *epitrichium*, consisting of flat cells, the nuclei of which stain readily, and a deep, named the *stratum germinativum*, consisting at first of cubical, but later of columnar, cells. By multiplication and differentiation of the cells of the stratum germinativum the different layers of the epidermis are developed. Towards the end of the third month the mesoderm condenses to form the corium, and at about the same time the subcutaneous areolar tissue is differentiated; in the fourth month the dermal papillæ begin to make their appearance. A considerable desquamation of the epidermis takes place, and this desquamated epidermis, mixed with sebaceous secretion, constitutes the *vernix caseosa*, with which the skin is smeared during the last three months of foetal life.

The *hairs* (fig. 127) originate as thickenings of the epidermis which grow obliquely downwards as solid buds into the corium, each bud consisting of an outer stratum of columnar cells and a core of polygonal cells. The deep end of each bud expands to form the hair-bulb which is moulded over a papilla of condensed mesoderm. The cells of the hair-bulb proliferate and form a cone of cells, from which the scapus or shaft of the hair and its inner sheath are developed. The hairs gradually lengthen by growth at the hair-bulb, and when they project on the surface they push before them the *epitrichium* which is broken up and shed.

The *sebaceous glands* originate as lateral outgrowths from the sides of the hair-buds, and, pushing their way into the mesoderm, divide into three or four oval or flask-shaped alveoli.

The rudiments of the *sudoriferous* or *sweat glands* make their appearance on the palms of the hands and soles of the feet in the fourth month, and closely resemble the rudiments of the hairs, each beginning as a solid downgrowth of the ectoderm.

The ectodermal downgrowth lengthens, and its deeper part coils on itself and forms the body of the gland. A lumen is developed in the downgrowth about the seventh month of foetal life, and opens on the surface by a duct which is lined by two layers of cells. In the secreting part of the gland the outer layer of cells is modified to form a stratum of smooth muscle-fibres which lies between the gland epithelium and the basement membrane. Many sudoriferous glands arise as ectodermal downgrowths from the superficial portions of the hair-follicles and later acquire independent openings on the surface of the skin.

The *mammary gland* may be looked upon as a collection of greatly modified sudoriferous glands; the epithelial lining of its ducts and alveoli is derived from the ectoderm, its supporting connective tissue from the mesoderm. On either side of the ventral surface of young embryos a thickened band of ectoderm, termed the *milk-ridge*, extends obliquely from the base of the fore-limb to the inguinal region near the middle line, and in some of the lower mammals (e.g. the sow) mammae are developed at intervals along this ridge. In man only one mamma, as a rule, is developed on either side of the middle line, but supernumerary glands or nipples are not infrequently found above or below the fully developed gland. The rudiment of the mamma appears as a thickening and subsequent downgrowth of the ectoderm; from this downgrowth between fifteen and twenty solid cords branch off, each cord representing a future lactiferous tubule and lobe of the gland. The deep ends of the cords subdivide in the mesoderm and form the gland alveoli. The region where the ectodermal thickening occurred is subsequently raised to form the nipple, and about the time of birth the tubules and alveoli become canalised. At the age of puberty, and in a greater degree towards the end of pregnancy, a marked enlargement of the gland, with the development of additional lobules and alveoli, takes place.

The rudiments of the *nails* can be seen in embryos of about 4.5 cm. in length, and appear as *primary nail-fields* of ectoderm on the dorsal surfaces of the terminal phalanges of the digits. At the proximal end and sides of each nail-field the epidermis is invaginated to form the nail-folds, while the opposite end, which will ultimately form the free end of the nail, is bounded by a shallow groove. The nail is developed from the posterior nail-fold and consists of modified stratum lucidum. The stratum corneum covers the nail and forms the *eponychium*; this disappears from the surface of the nail, with the exception of a narrow fold which overlaps the proximal part of the lunule of the nail.

FIG. 127.—Successive stages in the development of hair.

DEVELOPMENT OF THE NERVOUS SYSTEM AND SENSE-ORGANS

The nervous system is derived from the ectoderm and first appears as the neural groove on the dorsal aspect of the embryo (fig. 80). By the elevation and ultimate fusion of the neural folds, the groove is converted into the neural tube (fig. 82).

The anterior end of the tube expands to form the three primary brain-vesicles; the cavity of the tube is subsequently modified to form the ventricular cavities of the brain, and the central canal of the medulla spinalis; from the wall the nervous elements and the neuroglia of the brain and medulla spinalis are developed.

The medulla spinalis.—At first the wall of the neural tube is composed of a single layer of columnar ectodermal cells. The lateral parts of the wall soon thicken, while the dorsal and ventral parts remain thin, and are named the *roof- and floor-plates* (figs. 128, 130). A transverse section of the tube at this stage presents an oval outline and a slit-like lumen. The cells which constitute the wall of the tube proliferate rapidly, lose their cell-boundaries and form a syncytium consisting at first of dense protoplasm with closely packed nuclei, but later opening out and forming a loose meshwork with the cellular strands radiating from the central canal. Three layers of this syncytium may be defined—an internal or *ependymal*, an intermediate or *mantle*, and an external or *marginal* (fig. 128). The *ependymal layer* is ultimately converted into the *ependyma* of the central canal; the processes of its cells pass outwards towards the periphery of the medulla spinalis. The *marginal*

FIG. 128.—Transverse section of the medulla spinalis of a four weeks' embryo. (His.)

layer is devoid of nuclei, and later forms the supporting framework for the white funiculi of the medulla spinalis. The *mantle layer* represents the future grey columns of the medulla spinalis; in it the cells are differentiated into two sets, viz. (a) *spongioblasts* or young neuroglia-cells, and (b) *germinal cells*, which are the parents of the *neuroblasts* or young nerve-cells (fig. 129). The spongioblasts are at first connected to one another by filaments of the syncytium; in these, fibrils are developed, so that as the neuroglia cells become defined they exhibit their characteristic mature appearance with multiple processes proceeding from each cell. The germinal cells are large, round or oval, and first make their appearance between the ependymal cells on the sides of the central canal. They increase rapidly in number, so that by the fourth week they form an almost continuous layer on each side of the tube. No germinal cells are found in the roof- or floor-plates; the roof-plate retains, in certain regions of the brain, its epithelial character; elsewhere, its cells become spongioblasts. By subdivision the germinal cells give rise to the neuroblasts or young nerve-cells, which migrate outwards from the sides of the central canal into the mantle layer and neural crest, and at the same time become pear-shaped; the tapering part of the cell undergoes still further elongation, and forms the *axis-cylinder* of the cell.

The lateral walls of the medulla spinalis increase in thickness, and the central canal widens out near its dorsal extremity, and assumes a somewhat lozenge-shaped appearance. The widest part of the canal subdivides the lateral wall of the neural

tube into a *dorsal* or *alar*, and a *ventral* or *basal lamina* (fig. 130), a subdivision which extends forwards into the brain. The dorsal part of the canal is reduced to a mere slit which is subsequently obliterated by the approximation and fusion of its walls; the ventral part persists and forms the central canal of the adult medulla

FIG. 129.—Transverse section of the medulla spinalis of a human embryo at the beginning of the fourth week. (After His.) The left edge of the figure corresponds to the lining of the central canal.

spinalis. The caudal end of the canal exhibits a conical expansion which is known as the *terminal ventricle*.

The ventral part of the mantle layer increases in thickness, and on cross-section appears as a triangular patch between the marginal and ependymal layers. This thickening is the rudiment of the anterior column of grey substance, and contains

FIG. 130.—Transverse sections of the medulla spinalis of human embryos. A, about four and a half weeks old. B, about three months old. (His.)

many neuroblasts, the axis-cylinders of which pass out through the marginal layer and form the anterior roots of the spinal nerves (figs. 128, 130). The thickening of the mantle layer gradually extends in a dorsal direction, and forms the posterior column of grey substance. The axons of many of the neuroblasts in the alar lamina run forward, cross in the floor-plate to the opposite side of the medulla spinalis, and form the rudiment of the anterior white commissure.

About the end of the fourth week nerve-fibres appear in the marginal layer. The first to develop are the short intersegmental fibres from the neuroblasts in the mantle zone, and the fibres of the posterior roots of the spinal nerves which grow into the medulla spinalis from the cells of the spinal ganglia. By the sixth week the fibres of the posterior roots of the spinal nerves form a well defined *oval bundle* in the peripheral part of the alar lamina; this bundle increases in size, and spreading towards the middle line forms the rudiment of the posterior funiculus. The long intersegmental fibres begin to appear about the third month, and the cerebrospinal fibres about the fifth month. All nerve-fibres are at first destitute of medullary sheaths, and different groups of fibres receive their sheaths at different times—the anterior and posterior nerve-roots are medullated about the fifth month, the cerebrospinal fibres after the ninth month.

By the growth of the anterior columns of grey substance, and by the increase in size of the anterior funiculi, an anterior furrow is formed between the lateral halves of the medulla spinalis; this gradually deepens to form the anterior median fissure (fig. 130, B). The mode of formation of the posterior septum is somewhat uncertain. Many believe that it is produced by the growing together of the walls of the posterior part of the central canal and by the development from its ependymal cells of a septum of fibrillated tissue which separates the future funiculi graciles.

Up to the third month of foetal life the medulla spinalis occupies the entire length of the vertebral canal, and the spinal nerves pass outwards at right angles.

FIG. 131.—Two stages in the development of the neural crest in the human embryo. (Lenhossék.)

From this time onwards, the vertebral column grows more rapidly than the medulla spinalis, and the latter, being fixed above through its continuity with the brain, gradually assumes a higher position within the vertebral canal. By the sixth month the lower end of the medulla spinalis reaches only as far as the base of the sacrum; at birth it is on a level with the third lumbar vertebra, and in the adult with the lower border of the first or upper border of the second lumbar vertebra. A delicate filament, the *filum terminale*, extends from the lower end of the medulla spinalis as far as the first segment of the coccyx.

The spinal nerves.—Each spinal nerve is attached to the medulla spinalis by an anterior and a posterior root.

The fibres of the anterior or motor roots are formed by the axons

of the neuroblasts which lie in the ventral part of the mantle layer; these axons grow out through the overlying marginal layer into the myotomes of the primitive segments, and are ultimately aggregated to form the anterior nerve-roots (fig. 128).

The fibres of the posterior roots are developed from the cells of the spinal ganglia. Before the neural groove is closed to form the neural tube a ridge of ectodermal cells, the *ganglion-ridge* or *neural crest* (fig. 131), appears along the prominent margin of each neural fold. When the folds meet in the middle line the two ganglion-ridges fuse and form a wedge-shaped area along the line of closure of the tube. The cells of this area proliferate rapidly opposite the primitive segments and then migrate in a lateral and ventral direction to the sides of the neural tube, where they ultimately form a series of oval-shaped masses, the future spinal ganglia. These ganglia are arranged symmetrically on the two sides of the neural tube and, except in the region of the tail, are equal in number to the primitive segments. The cells of the ganglia, like the cells of the mantle layer, are of two kinds, viz. spongioblasts and neuroblasts. The spongioblasts develop into the neuroglial cells of the ganglia. The neuroblasts, at first round or oval in shape, soon assume the form of spindles the extremities of which gradually elongate into central and peripheral processes. The central processes grow medialwards and, becoming connected with the neural

tube, constitute the fibres of the posterior nerve-roots, while the peripheral processes grow lateralwards to mingle with the fibres of the anterior root in the spinal nerve. As development proceeds the original bipolar form of the cells changes; the two processes become approximated until they ultimately arise from a single stem in a T-shaped manner. The bipolar form is retained in the retina and in the ganglia

FIG. 182.—Reconstruction of the peripheral nerves of a human embryo of 10·2 mm. (After His.) (From Quain's Elements of Anatomy, vol. i., Embryology.)

The abducent nerve is not labelled, but is seen passing forwards to the eye under the mandibular and maxillary nerves.

of the acoustic nerve. More recent observers hold, however, that the T-form is derived from the branching of a single process which grows out from the cell.

Although many embryologists accept the views: (a) that every motor nerve-fibre is an independent outgrowth from a motor nerve-cell and secondarily becomes connected to its special myotome, and (b) that from the sensory nerve-cell a central process grows into the medulla spinalis or into the brain, and a peripheral one outwards to unite with the peripheral sense-organ supplied by the nerve, it is probable that the myotomes and the peripheral sense-organs are from the first connected with the central nervous system, and that this connexion is never lost. In *Lepidosiren*

paradoxa, J. Graham Kerr has traced back the development of the motor nerve trunk to a period in which it is represented by a bridge of soft granular protoplasm connecting the medulla spinalis and myotome at a stage when these structures are in close apposition.* As the myotome is pushed outwards it remains connected with the medulla spinalis by the ever-lengthening strand of nerve, which soon loses its granular protoplasmic character and assumes a fibrillated appearance. A similar condition probably exists regarding the development of sensory nerve-fibres, for Cameron and Milligan† have shown that in early embryonic life the cell-elements of the sense-epithelium of the auditory vesicle are connected with those of the hind-brain by a continuous tract of nucleated protoplasm (syncytium) which is never severed. This syncytium, at first undifferentiated, becomes fibrillated longitudinally to form a continuous tract of nerve-fibres (the future auditory nerve) uniting the sense-epithelium of the auditory organ with the hind-brain.

The anterior and posterior nerve-roots join immediately beyond the spinal ganglion to form the *spinal nerve*, which then divides into anterior, posterior, and visceral divisions. The anterior and posterior divisions proceed directly to their

FIG. 133.—Diagram to illustrate the alar and basal laminae of the brain vesicles. (His.)

FIG. 134.—Transverse section of the medulla oblongata of a human embryo. $\times 32$. (From Kollmann's *Entwicklungsgeschichte*.)

areas of distribution without further association with ganglion-cells (fig. 132). The visceral divisions are distributed to the thoracic, abdominal, and pelvic viscera, to reach which they pass through the sympathetic trunk, and many of the fibres of these divisions form arborisations around the ganglion-cells of this trunk. Visceral divisions are not given off from all the spinal nerves; they form two groups, viz. (a) *thoracolumbar*, from the first or second thoracic to the second or third lumbar nerves inclusive; and (b) *pelvic*, from the second and third, or third and fourth sacral nerves.

The Brain.—The brain is developed from the anterior end of the neural tube, which at an early period expands into the three primary cerebral vesicles (fig. 81). These are marked off from each other by intervening constrictions, and are named the *rhombencephalon* or *hind-brain*, the *mesencephalon* or *mid-brain*, and the *prosencephalon* or *fore-brain*—the first being continuous with the medulla spinalis. As the result of unequal growth of the different parts of the brain three flexures are formed and the brain bends on itself in a somewhat zigzag fashion; the two earliest flexures are concave ventrally and are associated with corresponding flexures of the whole head. The first appears in the region of the mid-brain, and is named the *ventral cephalic flexure* (fig. 137); the fore-brain bends in a ventral direction around the anterior end of the notochord and fore-gut until its floor lies almost

* 'On some points in the early development of motor nerve-trunks and myotomes in *Lepidosiren paradoxa*,' *Transactions of the Royal Society of Edinburgh*, vol. xli. part i. 1903-4.

† 'The development of the auditory nerve in vertebrates,' *Journal of Anatomy and Physiology*, vol. xliiv.

parallel with that of the hind-brain. The mid-brain is for a time the most prominent part of the brain, since its dorsal surface corresponds with the convexity of the flexure. The second bend appears at the junction of the hind-brain and medulla spinalis, and is termed the *cervical flexure* (fig. 137). It increases from the third to the end of the fifth week, when the hind-brain forms nearly a right angle with the medulla spinalis; after the fifth week erection of the head takes place and the cervical flexure diminishes and disappears. The third bend is named the *pontine flexure* (fig. 139), because it is found in the region of the future pons (Varolii). It differs from the other two in that (a) its convexity is forwards, and (b) it does not affect the head.

The lateral walls of the brain-tube, like those of the medulla spinalis, are divided by internal furrows into dorsal or alar and ventral or basal laminæ (figs. 133, 134).

The **rhombencephalon** or **hind-brain**.—The cavity of the hind-brain becomes the fourth ventricle. At the time when the ventral cephalic flexure makes its appearance, the hind-brain exceeds in length the combined lengths of the other two vesicles. Anteriorly it exhibits a constriction, the *isthmus rhombencephali* (fig. 133, Isthmus), which is best seen when the brain is viewed from the dorsal aspect. From the isthmus the brachia conjunctiva of the cerebellum and the

FIG. 135.—Transverse section of the medulla oblongata of a human embryo. (After His.)

anterior medullary velum are formed. The rest of the hind-brain consists of two parts, viz.: an upper, called the *metencephalon*, and a lower, the *myelencephalon*. The cerebellum is developed by a thickening of the roof, and the pons by a thickening in the floor and lateral walls of the metencephalon. The floor and lateral walls of the myelencephalon are thickened to form the medulla oblongata; its roof remains thin, and, retaining to a great extent its epithelial nature, is expanded in a lateral direction. Later, by the growth and backward extension of the cerebellum, the roof is folded inwards towards the cavity of the fourth ventricle; it assists in completing the dorsal wall of this cavity, and is also invaginated to form the ependymal covering of the choroid plexuses of the fourth ventricle. Above it is continuous with the posterior medullary velum; below, with the obex and ligulæ.

The development of the *medulla oblongata*, though resembling that of the medulla spinalis, exhibits one or two interesting modifications. At an early stage the myelencephalon consists of two lateral walls, connected across the middle line by floor- and roof-plates (figs. 134 and 135). Each lateral wall consists of an alar and a basal lamina, separated by an internal furrow, the remains of which are represented in the adult brain by the sulcus limitans on the rhomboid fossa. The contained cavity is more or less triangular in section, the base being formed by the roof-plate, which is thin and greatly expanded transversely. Pear-shaped neuroblasts are developed in the alar and basal laminæ, and their narrow stalks are elongated to form the axis-cylinders of the nerve-fibres. Opposite the furrow or boundary between the alar and basal laminæ a bundle of nerve-fibres attaches itself to the outer surface of the alar lamina. This is named the *tractus solitarius*

(fig. 135), and is formed by the sensory fibres of the glossopharyngeal and vagus nerves. It is the homologue of the *oval bundle* seen in the medulla spinalis, and, like it, is developed by an ingrowth of fibres from the ganglia of the neural crest.

FIG. 136.—Hind-brain of a human embryo of three months, viewed from behind and partly from the right side. (From model by His.)

alar lamina and its rhombic lip, neuroblasts migrate into the basal lamina, where some are aggregated to form the olivary nuclei, while many send their axis-cylinders through the floor-plate to the opposite side, and thus constitute the rudiment of the raphe of the medulla oblongata. By means of this thickening of the ventral portion, the motor nuclei are buried deeply in the interior, and in the adult are found close to the rhomboid fossa. This is still further accentuated: (a) by the development of the pyramids, which are formed about the fourth month by the downward growth of the motor fibres from the cerebral cortex; and (b) by the fibres which pass to and from the cerebellum. On the rhomboid fossa six temporary furrows or *rhombic grooves* appear. They bear a definite relationship to certain of the cerebral nerves; thus, from before backwards, the first and second grooves overlie the nucleus of the trigeminal; the third, that of the facial; the fourth, that of the abducent; the fifth, that of the glossopharyngeal; and the sixth, that of the vagus.

The pons is developed from the ventrolateral wall of the metencephalon by a process similar to that which has been described for the medulla oblongata.

At first it is applied to the outer surface of the alar lamina, but is soon buried by the growth over it of the neighbouring parts. By the fifth week the dorsal part of the alar lamina bends in a lateral direction along its entire length, to form what is termed the *rhombic lip* (figs. 135, 139). Within a few days this lip adheres to, and unites with, the outer surface of the main part of the alar lamina, and so covers in the tractus solitarius and also the spinal root of the trigeminal nerve.

Neuroblasts accumulate in the mantle layer; those in the basal lamina correspond with the cells in the anterior grey column of the medulla spinalis, and, like them, give origin to motor nerve-fibres; in the medulla oblongata they are, however, arranged in groups or nuclei, instead of forming a continuous column. From the

FIG. 137.—Exterior of the brain of a human embryo of four and a half weeks. (From model by His.)

The *cerebellum* is developed in the roof of the anterior part of the hind-brain (figs. 136 to 141). The alar laminae of this part increase in thickness and form two lateral plates which fuse in the middle line and produce a thick lamina which roofs in the upper part of the cavity of the hind-brain vesicle; this lamina constitutes the rudiment of the cerebellum, the outer surface of which is originally smooth and convex. The flocculus and nodule are developed from the rhombic lip, and are recognisable as separate portions before any of the other cerebellar lobules. The fissures of the cerebellum appear first in the vermis and floccular region, and traces of them are found during the third month; the fissures on the cerebellar hemispheres do not appear till the fifth month. The primitive fissures are not developed in the order of their relative size in the adult—thus the horizontal sulcus in the fifth month is merely a shallow groove. The best marked of the early fissures are: (a) the *fissura prima* between the developing culmen and declive, and (b) the *fissura secunda* between the future pyramid and uvula. The groove produced by the bending over of the rhombic lip is here known as the *floccular fissure*; when the two lateral walls fuse, the right and left floccular fissures join in the middle line, and their central part becomes the *postnodular fissure*.

On the ventricular surface of the cerebellar lamina a transverse furrow, the *incisura fastigii*, appears and then deepens to form the tent-like recess of the roof of the fourth ventricle. The rudiment of the cerebellum at first projects in a dorsal direction; but, by the backward growth of the cerebrum, it is folded downwards and somewhat flattened, and the thin roof-plate of the fourth ventricle, originally continuous with the posterior border of the cerebellum, is projected inwards towards the cavity of the ventricle.

The *mesencephalon* or *mid-brain*.—The mid-brain (figs. 137 to 141) exists for a time as a thin-walled cavity of some size, and is separated by slight constrictions from the isthmus rhombencephali behind, and from the fore-brain in front. Its cavity becomes relatively reduced in diameter, and forms the cerebral aqueduct of the adult brain. The basal laminae of the hind-brain increase in thickness to form the cerebral peduncles, which are at first of small size, but rapidly enlarge after the fourth month. Many of the neuroblasts of these laminae are grouped in relation to the sides and floor of the cerebral aqueduct, and constitute the nuclei of the oculomotor and trochlear nerves, and of the mesencephalic root of the trigeminal nerve; others are aggregated to form the red nuclei. By a similar thickening process the alar laminae are developed into the quadrigeminal lamina. The dorsal part of the wall expands, and for a time presents an internal median furrow and a corresponding external ridge; these, however, disappear, and the latter is replaced by a groove. Subsequently two oblique furrows extend medialwards and backwards, and the thickened lamina is thus subdivided into the superior and inferior colliculi.

The *prosencephalon* or *fore-brain*.—A transverse section of the early fore-brain shows the same parts as are displayed in similar sections of the medulla spinalis and medulla oblongata, viz. a pair of thick lateral walls connected by thin floor- and roof-plates. Moreover, each lateral wall is divided into a dorsal or alar and a ventral or basal lamina separated internally by a furrow termed

FIG. 138.—Brain of a human embryo of four and a half weeks, showing the interior of fore-brain. (From model by His.)

the *sulcus of Monroe*. This sulcus ends anteriorly at the medial end of the optic stalk, and in the adult brain is retained as a slight groove extending backwards from the interventricular foramen to the cerebral aqueduct.

At a very early period—in some animals before the closure of the cranial part of the neural tube—two lateral diverticula, the *optic vesicles*, appear, one on either side of the fore-brain; for a time they communicate with the cavity of the fore-brain by relatively wide openings. The peripheral parts of the vesicles expand, while the proximal parts are reduced to tubular stalks, the *optic stalks*. The optic vesicle gives rise to the retina and the epithelium on the back of the ciliary body and iris; the optic stalk is invaded by nerve-fibres to form the optic nerve. The fore-brain then grows forwards, and from the alar laminae of this front portion the cerebral hemispheres originate as diverticula which rapidly expand to form two large pouches, one on either side. The cavities of these diverticula are the rudiments of the lateral ventricles; they communicate with the median part of the fore-brain cavity by

FIG. 139.—Exterior of the brain of a human embryo of five weeks. The roof of the hind-brain has been removed. (From model by His.)

relatively wide openings, which ultimately form the interventricular foramen (foramen of Monroe). The median portion of the wall of the fore-brain vesicle consists of a thin lamina, the *lamina terminalis* (figs. 141, 144), which stretches from the interventricular foramen to the recess at the base of the optic stalk. The anterior part of the fore-brain, including the rudiments of the cerebral hemispheres, is named the *telencephalon*, and the posterior portion the *diencephalon*; both contribute to the formation of the third ventricle.

The diencephalon.—From the alar lamina of the diencephalon, the thalamus, metathalamus, and epithalamus are developed. The *thalamus* (figs. 137 to 141) arises as a thickening which involves the anterior two-thirds of the alar lamina. The two thalami are visible, for a time, on the surface of the brain, but are subsequently hidden by the cerebral hemispheres which grow backwards over them. The thalami extend medialwards and gradually narrow the interval between them into a slit-like cavity which forms the greater part of the third ventricle; their medial surfaces ultimately adhere, in part, to each other, and the *intermediate mass* of the ventricle is developed across the area of contact. The *metathalamus* comprises the medial and lateral geniculate bodies which originate as slight outward bulgings of the alar lamina. In the adult the lateral geniculate body appears as an eminence on the lateral part of the posterior end of the thalamus, while the medial lies under cover of the pulvinar

of the thalamus. The *epithalamus* includes the pineal body, the posterior commissure, and the trigonum habenulæ. The pineal body arises as a bilateral evagination of the roof-plate immediately in front of the mid-brain; only the left portion persists in vertebrates, and it becomes solid with the exception of its proximal part, which forms the recessus pinealis. The pineal body consists essentially of (a) a distal part representing a rudimentary eye, and (b) a proximal part which is glandular in nature; only this latter portion is represented in man. The posterior commissure is formed by the ingrowth of fibres into the depression behind and below the pineal evagination, and the trigonum habenulæ is developed in front of the pineal recess.

From the basal laminæ of the diencephalon the *pars mamillaris hypothalami* is developed; this comprises the corpora mamillaria and the posterior part of the tuber cinereum. The corpora mamillaria arise as a single thickening, which is divided by a median furrow during the third month.

FIG. 140.—Interior of the brain of a human embryo of five weeks. The roof of the hind-brain has been removed. (From model by His.)

The roof-plate of the diencephalon, in front of the pineal body, remains thin and epithelial in character, and is subsequently invaginated by the chorioid plexuses of the third ventricle.

The *telencephalon*.—This consists of a median portion and two lateral diverticula. The median portion forms the anterior part of the cavity of the third ventricle, and is closed below and in front by the lamina terminalis. The lateral diverticula consist of outward pouchings of the alar laminæ; the cavities represent the future lateral ventricles, and their walls the nervous matter of the cerebral hemispheres. The roof-plate of the telencephalon remains thin, and is continuous in front with the lamina terminalis and behind with the roof-plate of the diencephalon. In the basal laminæ and floor-plate the *pars optica hypothalami* is developed; this comprises the anterior part of the tuber cinereum, the infundibulum and posterior lobe of the hypophysis, and the optic chiasma. The anterior part of the tuber cinereum is derived from the posterior part of the floor of the telencephalon; the infundibulum and posterior lobe of the hypophysis arise as a downward diverticulum from the floor. The most dependent part of the diverticulum becomes solid and forms the posterior lobe of the hypophysis; the anterior lobe of the hypophysis is developed from a diverticulum of the ectodermal lining of the stomodæum (page 132). The optic chiasma is formed by the meeting and partial

decussation of the optic nerves, which subsequently grow backwards as the optic tracts and end in the diencephalon.

The *cerebral hemispheres* arise as diverticula of the alar laminae of the telencephalon (figs. 137 to 141); they increase rapidly in size and ultimately overlap the structures developed from the mid- and hind-brains. This great expansion of the hemispheres is a characteristic feature of the brains of mammals, and attains its maximum development in the brain of man. Elliot Smith divides each cerebral hemisphere into three fundamental parts, viz. the rhinencephalon, the corpus striatum, and the neopallium.

The *rhinencephalon* (figs. 139 to 142) represents the oldest part of the telencephalon, and forms almost the whole of the hemisphere in fishes, amphibians, and reptiles. In man it is feebly developed in comparison with the rest of the hemisphere, and comprises the following parts, viz. the olfactory lobe (consisting of the

FIG. 141.—Median sagittal section of brain of a human embryo of three months. (From model by His.)

olfactory tract and bulb, and the trigonum olfactorium), the anterior perforated substance, the septum pellucidum, the subcallosal, supracallosal, and dentate gyri, the fornix, the hippocampus, and the uncus. The rhinencephalon appears as a longitudinal elevation, with a corresponding internal furrow, on the under surface of the hemisphere close to the lamina terminalis; it is separated from the lateral surface of the hemisphere by a furrow, the *external rhinal fissure*, and is continuous behind with that part of the hemisphere which will ultimately form the anterior end of the temporal lobe. The elevation is divided by a groove into an anterior and a posterior part. The anterior grows forwards as a hollow stalk the lumen of which is continuous with the anterior part of the ventricular cavity. During the third month the stalk becomes solid and forms the rudiment of the olfactory bulb and tract; a strand of gelatinous tissue in the interior of the bulb indicates the position of the original cavity. From the posterior part the anterior perforated substance and the pyriform lobe are developed; at the beginning of the fourth month the latter forms a curved elevation continuous behind with the medial surface of the temporal lobe, and consisting, from before backwards, of the gyrus olfactorius lateralis, gyrus ambiens, and gyrus semilunaris, parts which in the adult brain are represented by the lateral root of the olfactory tract and the uncus. The

position and connexions of the remaining portions of the rhinencephalon are described with the anatomy of the brain.

The *corpus striatum* (figs. 138, 140) appears in the fourth week as a triangular thickening of the floor of the telencephalon between the optic recess and the interventricular foramen, and continuous behind with the thalamic part of the diencephalon. It increases in size, and by the second month forms a swelling in the floor of the future lateral ventricle; this swelling reaches as far as the posterior end of the primitive hemisphere, and when this part of the hemisphere grows backwards and downwards to form the temporal lobe, the posterior part of the corpus striatum is carried into the roof of the inferior horn of the ventricle, where it is seen as the tail of the caudate nucleus in the adult brain. During the fourth and fifth months the corpus striatum becomes incompletely subdivided by the fibres of the internal capsule into two masses, an inner, the caudate nucleus, and an outer, the lentiform nucleus. In front, the corpus striatum is continuous with the anterior perforated substance; laterally it is confluent for a time with that portion of the wall of the vesicle which is developed into the insula, but this continuity is subsequently interrupted by the fibres of the external capsule.

The *neopallium* (fig. 143) forms the remaining, and by far the greater part of the cerebral hemisphere. It consists, at an early stage, of a relatively large, more or less hemispherical cavity—the primitive lateral ventricle—enclosed by a thin wall from which the cortex of the hemisphere is developed. The vesicle expands in all directions, but more especially upwards and backwards, so that by the third month the hemispheres cover the diencephalon, by the sixth they overlap the mid-brain and by the eighth the hind-brain.

The median lamina uniting the two hemispheres does not share in their expansion, and thus the hemispheres are separated by a deep cleft, the forerunner of the longitudinal fissure, and this cleft is occupied by a septum of mesodermal tissue which constitutes the primitive falx cerebri. Coincidentally with the expansion of the vesicle, its cavity is drawn out into three prolongations which represent the horns of the future lateral ventricle; the hinder end of the vesicle is carried downwards and forwards and forms the inferior horn; the posterior horn is produced somewhat later, in association with the backward growth of the occipital lobe of the hemisphere. The roof-plate of the primitive fore-brain remains thin and of an epithelial character; it is invaginated into the lateral ventricle along the medial wall of the hemisphere. This invagination constitutes the chorioidal fissure, and extends from the interventricular foramen to the posterior end of the vesicle. Mesodermal tissue, continuous with that of the pia mater, and carrying blood-vessels with it, spreads between the two layers of the invaginated fold and forms the rudiment of the tela chorioidea; the margins of the tela become highly vascular and form the chorioid plexuses which for some months almost completely fill the ventricular cavities; the tela at the same time invaginates the epithelial roof of the diencephalon and there forms the chorioid plexuses of the third ventricle. By the downward and forward growth of the posterior end of the vesicle to form the temporal lobe the chorioidal fissure finally reaches from the interventricular foramen to the extremity of the inferior horn of the ventricle.

FIG. 142.—Inferior surface of the brain of an embryo at the beginning of the fourth month. (Kollmann.)

Parallel with but above and in front of the chorioidal fissure the medial wall of the cerebral vesicle becomes folded lateralwards and gives rise to the *hippocampal fissure* on the medial surface and to a corresponding elevation, the *hippocampus*, within the ventricular cavity. The grey or ganglionic covering of the wall of the vesicle ends at the inferior margin of the fissure in a thickened edge; beneath this the marginal or reticular layer (future white substance) is exposed and its lower thinned edge is continuous with the epithelial invagination covering the chorioid plexus (fig. 143). As a result of the later downward and forward growth of the temporal lobe the hippocampal fissure and the parts associated with it extend from the interventricular foramen to the end of the inferior horn of the ventricle. The thickened edge of grey substance becomes the gyrus dentatus, the fasciola cinerea and the supra- and sub-callosal gyri, while the free edge of the white substance forms

FIG. 143.—Diagrammatic coronal section of the brain to show relations of the neopallium. (After His.) (From Quain's Elements of Anatomy, vol. i., Embryology.)

the fimbria hippocampi and the body and crus of the fornix. The corpus callosum is developed within the arch of the hippocampal fissure, and the upper part of the fissure forms, in the adult brain, the callosal fissure on the medial surface of the hemisphere.

The commissures (fig. 144).—The development of the posterior commissure has already been referred to (page 95). The great commissures of the hemispheres, viz. the corpus callosum, the fornix, and anterior commissure, arise from the lamina terminalis. About the fourth month a small thickening appears in this lamina, immediately in front of the interventricular foramen. The lower part of this thickening is soon separated, and nerve-fibres appear in it to form the anterior commissure. The upper part continues to grow with the hemispheres, and is invaded by two sets of fibres. Transverse fibres, extending between the hemispheres, pass into its dorsal part, which is now differentiated as the corpus callosum. Into the ventral part longitudinal fibres from the hippocampus pass to the lamina terminalis, and through that structure to the corpora mamillaria; these fibres constitute the fornix. A small portion, lying antero-inferiorly between the corpus callosum and fornix, is not invaded by the commissural fibres; it remains thin, and later, a cavity, the cavity of the septum pellucidum, forms in its interior.

Fissures and Sulci.—The outer surface of the cerebral hemisphere is at first smooth, but later exhibits a number of elevations or convolutions, separated from

each other by fissures and sulci, most of which make their appearance during the sixth or seventh months of foetal life. The term *fissure* is applied to such grooves as

FIG. 144.—Median sagittal section of the brain of a human embryo of four months. (Marchand.)

involve the entire thickness of the cerebral wall, and produce corresponding eminences in the lateral ventricle, while the *sulci* affect only the superficial part of the wall, and produce no such eminences. The fissures comprise the *chorioid* and *hippocampal* already described, and two others, viz. the *calcarine* and *collateral*, which give rise to the swellings known respectively as the *calcar avis* and the *collateral eminence* in the lateral ventricle. Of the sulci the following may be referred to, viz. the *central sulcus* (*fissure of Rolando*), which is developed in two parts; the *intraparietal sulcus* in four parts; and the *cingulate sulcus* in two or three parts. The *lateral cerebral* or *Sylvian fissure* differs from the others in its mode of development. About the third month a depression, the *Sylvian fossa*, appears on the lateral surface of the hemisphere (fig. 145); this fossa corresponds with the position of the corpus striatum, and its floor is moulded to form the cortex of the insula. The intimate connexion which exists between the deep surface of the cortex of the insula and the corpus striatum prevents the insular part of the hemisphere wall from expanding at the same rate as the portions which surround it, with the result that they gradually grow over and cover the insula, and constitute the temporal, parietal, frontal, and orbital opercula of the adult brain. The frontal and orbital opercula are the last to form, but by the end of the first year after birth the insula is completely submerged by the approximation of the opercula. The fissures separating the opposed margins of the opercula constitute the composite lateral cerebral fissure.

FIG. 145.—(Lateral surface of the cerebral hemisphere of a human embryo of about five months.

If a section across the wall of the hemisphere about the sixth week be examined microscopically it will be found to consist of a thin marginal or reticular layer, a thick ependymal layer, and a thin intervening mantle layer. Neuroblasts from the ependymal and mantle layers migrate into the deep part of the marginal layer and form the cells of the cerebral cortex. By the sixth month the middle cell-lamina has attained one-half, and the inner cell-lamina three-fourths of their adult thickness; the outer cell-lamina is the last to develop. The nerve fibres which form the underlying white substance of the hemispheres consist at first of outgrowths from the cells of the corpora striata and thalami; the fibres from the cells of the cortex are added later. Medullation of these fibres begins about the time of birth and continues until puberty.

A summary of the parts derived from the brain vesicles is given in the following table:—

Rhombencephalon or hind-brain	1. Myelencephalon	Medulla oblongata. Lower part of fourth ventricle.
	2. Metencephalon	Pons. Cerebellum. Intermediate part of fourth ventricle.
	3. Isthmus rhombencephali	Anterior medullary velum. Brachia conjunctiva cerebelli. Upper part of fourth ventricle.
Mesencephalon or mid-brain		Cerebral peduncles. Lamina quadrigemina. Cerebral aqueduct.
Prosencephalon or fore-brain	1. Diencephalon	Thalamus. Metathalamus. Epithalamus. Pars mammillaris hypothalami. Posterior part of third ventricle.
		Anterior part of third ventricle.
	2. Telencephalon	Pars optica hypothalami. Cerebral hemispheres. Lateral ventricles. Interventricular foramen.

The cerebral nerves.—With the exception of the olfactory, optic, and acoustic nerves, which will be specially considered, the cerebral nerves are developed in a similar manner to the spinal nerves (page 88). The sensory or afferent nerves are derived from the cells of the ganglion-rudiments of the neural crest. The central processes of these cells form the roots of the nerves, while the peripheral processes constitute their fibres of distribution (fig. 132). It has been seen, in considering the development of the medulla oblongata (page 91), that the *tractus solitarius* (fig. 147), derived from the fibres which grow inwards from the ganglion-rudiments of the glossopharyngeal and vagus nerves, is the homologue of the *oval bundle* in the medulla spinalis which has its origin in the posterior nerve-roots. The motor nerves arise as outgrowths of the neuroblasts situated in the basal laminae of the mid- and hind-brain. While, however, the spinal motor nerve-roots arise in one series from the basal lamina, the cerebral motor nerves are grouped into two sets, according as they spring from the medial or lateral parts of the basal lamina. To the former set belong the oculo-motor, trochlear, abducent, and hypoglossal nerves; to the latter, the accessory, and the motor fibres of the trigeminal, facial, glossopharyngeal, and vagus nerves (figs. 146, 147).

The sympathetic system.—The ganglion-cells of the *sympathetic system* are derived from the cells of the neural crests. These crests move forwards along the sides of the neural tube and become segmented to form the spinal ganglia; certain cells detach themselves from the ventral margins of the crests and migrate towards the sides of the aorta, where some of them are grouped to form the ganglia of the sympathetic trunks, while others undergo a further migration and form

the ganglia of the prevertebral and visceral plexuses. The ciliary, sphenopalatine, otic, and submaxillary ganglia are probably formed by groups of cells which have migrated from that part of the neural crest which gives rise to the semilunar ganglion.

Chromaffin organs.—The tissue from which the sympathetic ganglia are formed is at first a syncytium of cells termed sympathochromaffin cells, but later two kinds of cells become differentiated from it; the smaller cells (sympathoblasts) are transformed into the sympathetic nerve-cells, the larger become chromaffin cells, and, separating from the others, accumulate to form the chromaffin organs. In the gangliated trunk of the sympathetic the chromaffin bodies are situated in depressions in the ganglia. In connexion with certain, but not all, of the secondary plexuses of the sympathetic system chromaffin organs are found; the largest members of this series are the *aortic bodies*, which lie along the sides of the abdominal aorta between the superior mesenteric and common iliac arteries; to this group belong also the *carotid glomera* (carotid bodies). After birth the chromaffin organs degenerate and can no longer be isolated by gross dissection, but chromaffin tissue can be recognised with the microscope in the sites originally occupied by them.

The suprarenal glands.—Each suprarenal gland consists of a cortical portion derived from the coelomic epithelium and a medullary portion originally composed of sympathochromaffin tissue. The cortical portion is first recognisable about

FIG. 146.—Transverse section of the medulla oblongata of a human embryo. $\times 32$. (From Kollmann's *Entwicklungsgeschichte*.)

FIG. 147.—Transverse section of the medulla oblongata of a human embryo. (After His.)

the beginning of the fourth week as a series of buds from the coelomic cells at the root of the mesentery. Later it becomes completely separated from the coelomic epithelium and forms a suprarenal ridge projecting into the coelom between the mesonephros and the root of the mesentery. Into this cortical portion cells from the neighbouring masses of sympathochromaffin tissue migrate along the line of its central vein to reach and form the medullary portion of the gland.

The Nose.—The development of the nose has already been considered (pages 79 to 82).

The *olfactory nerves* are developed from the cells of the ectoderm which line the olfactory pits; these cells undergo proliferation and give rise to what are termed

FIG. 148.—Transverse section of the head of a chick embryo of forty-eight hours' incubation. (From Duval's Atlas d'Embryologie.)

the *olfactory cells* of the nose. The axons of these cells grow into the overlying olfactory bulb and form the olfactory nerves.

The Eye.—The rudiments of the eyes appear as a pair of hollow diverticula from the lateral aspects of the fore-brain. These diverticula are visible before the closure of the anterior neuropore; after its closure they are known as the *optic vesicles*. They project towards the sides of the head, and the peripheral part of

FIG. 149.—Transverse section of the head of a chick embryo of fifty-two hours' incubation. (From Duval's Atlas d'Embryologie.)

each expands to form the *optic bulb*, while the proximal part remains narrow and constitutes the *optic stalk* (figs. 148, 149). A small area of ectoderm overlying the optic bulb becomes thickened, and ultimately separated as the *lens vesicle*, or rudiment of the crystalline lens. The outer wall of the optic bulb increases in thickness and undergoes invagination so that the bulb is converted into a cup, the *optic cup*, consisting of two strata of cells (fig. 149). These two strata are continuous with each other at the cup-margin, which ultimately overlaps the front of the lens and reaches as far forward as the future aperture of the pupil. The invagination

is not limited to the outer wall of the bulb, but involves also its postero-inferior surface and extends in the form of a groove for some distance along the optic stalk, and thus, for a time, a gap or fissure, the *chorioid fissure*, exists in the lower part of the cup (fig. 150). Through the groove and fissure the mesoderm extends into the optic stalk and cup, and in this mesoderm an artery is developed; during the seventh week the groove and fissure close, and the artery forms the central artery of the retina. Sometimes the chorioid fissure persists, and when this occurs the chorioid and iris in the region of the fissure remain undeveloped, giving rise to the condition known as *congenital coloboma* of the chorioid or iris.

The retina is developed from the optic cup. The outer stratum of the cup persists as a single layer of cells; these cells assume a columnar shape, acquire pigment,

and form the pigmented layer of the retina; the pigment first appears in the cells near the edge of the cup. The cells of the inner stratum proliferate and form a

- FIG. 150.—Optic cup and chorioidal fissure seen from below, from a human embryo of about four weeks. (Kollmann.)

layer of considerable thickness from which the nervous elements and the sustentacular fibres of the retina, together with a portion of the vitreous body, are developed. In the portion of the cup which overlaps the lens the inner stratum is

- FIG. 151.—Section through the eye of an eighteen days' embryo rabbit. $\times 30$ (Kölliker.)

not differentiated into nervous elements, but persists as a layer of columnar cells which, together with the pigmented layer, form the *pars ciliaris* and *pars iridica retinae*.

The cells of the inner or retinal layer of the optic cup differentiate into spongioblasts and germinal cells, and the latter by their subdivisions give rise to neuroblasts. From the spongioblasts the sustentacular fibres of Müller, the outer and inner limiting membranes, together with the ground-work of the molecular layers of the retina, are formed. The neuroblasts become arranged to form the ganglionic and nuclear layers. The layer of rods and cones is first developed in the central part of the optic cup, and from there gradually extends towards the cup margin. All the layers of the retina are completed by the eighth month of fetal life.

The optic stalk is converted into the optic nerve by the obliteration of its cavity and the growth of nerve-fibres into it. Most of these fibres are centripetal, and

FIG. 152.—Sagittal section of the eye of a human embryo of six weeks. (Kollmann.)

are the axons of the nerve-cells of the ganglionic layer of the retina, but a few are centrifugal and are derived from nerve-cells in the brain. The fibres of the optic nerve receive their medullary sheaths about the tenth week after birth. The optic chiasma is formed by the meeting and partial decussation of the fibres of the two optic nerves. Behind the chiasma the fibres are continued backwards as the optic tracts to the thalami and mesencephalon.

The crystalline lens is developed from the lens-vesicle, which recedes within the margin of the cup, and becomes separated from the overlying ectoderm by mesoderm. The cells forming the posterior wall of the vesicle lengthen and are converted into the lens-fibres, which grow forward and fill up the cavity of the vesicle (fig. 151). The cells forming the anterior wall retain their cellular character, and form the epithelium on the anterior surface of the fully developed lens. By the second month the lens is invested by a vascular mesodermal capsule, the *capsula vasculosa lentis*, the anterior part of which, covering the front of the lens, is named

the *pupillary membrane*; the blood-vessels supplying the posterior part of this capsule are derived from the hyaloid artery; those for the anterior part from the anterior ciliary arteries. By the sixth month all the vessels of the capsule are atrophied except the hyaloid artery, which disappears during the ninth month of fetal life; after birth the position of this artery is indicated by the hyaloid canal, which reaches from the optic disc to the posterior surface of the lens. With the loss of its blood-vessels the capsula vasculosa lentis disappears, but sometimes the pupillary membrane persists at birth, giving rise to the condition termed *congenital atresia of the pupil*.

The vitreous body is developed between the lens and the optic cup. The lens-rudiment and the optic vesicle are at first in contact with each other, but after the closure of the lens-vesicle and the formation of the optic cup the former is withdrawn from the retinal layer of the cup; the two, however, remain connected by a network

FIG. 153.—Section of the developing eye of a trout. (Szily.)

of delicate protoplasmic processes. This network, derived partly from the cells of the lens and partly from those of the retinal layer of the cup, constitutes the primitive vitreous body (figs. 152, 153). At first these protoplasmic processes spring from the whole of the retinal layer of the cup, but later are limited to the ciliary region, where by a process of condensation they appear to form the zonula ciliaris. The mesoderm which enters the cup through the chorioidal fissure and around the equator of the lens becomes intimately united with this reticular tissue, and contributes to form the vitreous body, which is therefore derived partly from the ectoderm and partly from the mesoderm.

The anterior chamber of the eye appears as a cleft in that part of the mesoderm which intervenes between the lens and the ectoderm. The layer of mesoderm in front of the cleft forms the substantia propria of the cornea, that behind the cleft the stroma of the iris and the pupillary membrane. The fibres of the Ciliaris muscle are derived from the mesoderm, but those of the Sphincter and Dilatator pupillæ are of ectodermal origin, being developed from the cells of the pupillary part of the optic cup.

The sclera and chorioid are derived from the mesoderm surrounding the optic cup.

The eyelids are formed as small cutaneous folds (figs. 149, 150). About the middle of the third month their edges come together and unite in front of the cornea; they remain united until about the end of the sixth month.

The lacrimal sac and nasolacrimal duct result from a thickening of the ectoderm in the groove (*naso-optic furrow*) between the lateral nasal and maxillary processes. This thickening forms a solid cord of cells which sinks into the mesoderm; during the third month the central cells of the cord break down, and a lumen, the nasolacrimal duct, is established. The lacrimal ducts arise as buds from the upper part of the cord of cells and secondarily establish openings (*puncta lacrimalia*) on the margins of the lids. The epithelium of the cornea and conjunctiva, and that which lines the ducts and alveoli of the lacrimal gland, is of ectodermal origin, as are also the eyelashes and the lining cells of the glands which open on the margins of the lids.

FIG. 154.—Section through the head of a human embryo, about twelve days old, in the region of the hind-brain. (Kollmann.)

FIG. 155.—Section through the hind-brain and auditory vesicles of an embryo more advanced than that of fig. 154. (After His.)

FIG. 156.—Left auditory vesicle of a human embryo of four weeks, seen from the outer surface. (W. His, jun.)

FIG. 157.—Left auditory vesicle of a human embryo of five weeks, seen from the outer surface. (W. His, jun.)

The ear.—The first rudiment of the internal ear appears shortly after that of the eye, in the form of a patch of thickened ectoderm, the *auditory plate*, over the region of the hind-brain. The auditory plate is invaginated and converted into the *auditory pit* (fig. 154). The mouth of the pit is then closed, and thus a shut sac, the *auditory vesicle* or *otocyst*, is formed (fig. 155); from it the epithelial lining of the membranous labyrinth is derived. The vesicle assumes a flask-shape, and the neck of the flask is obliterated (fig. 156). From the vesicle certain diverticula are given off which form the various parts of the membranous labyrinth. One from the middle part forms the ductus and saccus endolymphaticus. A second, from the anterior end, elongates, and forms the coiled tube of the cochlear duct, the proximal or vestibular extremity of which is subsequently constricted to form the

canalis reuniens. Three others appear as disc-like evaginations on the surface of the vesicle; the central parts of the walls of the discs coalesce and disappear, while the peripheral portions persist to form the semicircular ducts; of these the superior is the first, and the lateral the last, to be completed (fig. 157). The central part of the vesicle represents the membranous vestibule, and is subdivided by a constriction into a smaller ventral part, the saccule, and a larger dorsal and posterior part, the utricle (fig. 158). This subdivision is effected by a fold which extends deeply into the proximal part of the ductus endolymphaticus, with the result that the utricle and saccule ultimately communicate with each other by means of a Y-shaped canal. The saccule opens into the cochlear duct, through the canalis reuniens, and the semicircular ducts communicate with the utricle.

The mesoderm surrounding the various parts of the epithelial labyrinth is converted into a cartilaginous ear-capsule, and this is finally ossified to form the bony labyrinth. The portion of the capsule which envelopes the semicircular canals chondrifies before that which surrounds the cochlea. For a time the cartilaginous capsule is incomplete, and the cochlear, vestibular, and genicular ganglia are situated in the gap between its canalicular and cochlear parts. These ganglia are soon covered by an outgrowth of cartilage and at the same time the facial nerve is bridged by a growth of cartilage from the cochlear to the canalicular parts of the capsule. Between the cartilaginous capsule and the epithelial wall of the labyrinth a stratum of embryonic connective tissue is established, and in it the perilymphatic spaces are developed. Streeter* states that the rudiment of the vestibular perilymphatic space, or *periotic cistern* as he suggests this space should be named, can be seen in an embryo of from 30 to 40 mm. in length, in the reticulum between the saccule and the fenestra vestibuli. The scala tympani is next developed, and begins opposite the fenestra cochleæ. The scala vestibuli, the last to appear, is developed as an extension downwards of the vestibular perilymphatic space. The two scalæ gradually extend along the ductus cochlearis and when they reach the tip of the duct, a free opening is developed between them, and this represents the helicotrema.

FIG. 159.—Tubercles from which the different parts of the auricula are developed. (His.)

- 1, 2. Tubercles on mandibular arch. 3. Tubercle above groove. 3, c. Prolongation of 3 downwards. 4, 5, 6. Tubercles on hyoid arch. o.v. Auditory vesicle.

The modiolus and osseous spiral lamina of the cochlea are not preformed in cartilage but are ossified directly from connective tissue.

The auditory tube and tympanic cavity were formerly regarded as being derived from the first pharyngeal pouch, but J. Ernest Frazer† has recently pointed out

FIG. 158.—Left membranous labyrinth of a human embryo of 30 mm. (From model by W. His, jun.)

These ganglia are soon covered by an outgrowth of cartilage and at the same time the facial nerve is bridged by a growth of cartilage from the cochlear to the canalicular parts of the capsule. Between the cartilaginous capsule and the epithelial wall of the labyrinth a stratum of embryonic connective tissue is established, and in it the perilymphatic spaces are developed. Streeter* states that the rudiment of the vestibular perilymphatic space, or *periotic cistern* as he suggests this space should be named, can be seen in an embryo of from 30 to 40 mm. in length, in the reticulum between the saccule and the fenestra vestibuli. The scala tympani is next developed, and begins opposite the fenestra cochleæ. The scala vestibuli, the last to appear, is developed as an extension downwards of the vestibular perilymphatic space. The two scalæ gradually extend along the ductus cochlearis and when they reach the tip of the duct, a free opening is developed between them, and this represents the helicotrema.

* *American Journal of Anatomy*, vol. xxi.

† *Journal of Anatomy and Physiology*, vol. xlviii.

that they are developed from a recess, the *tubotympanic recess*, between the first and third visceral arches, the floor of the recess consisting of the first and second arches and the first and second pharyngeal pouches. By the forward growth of the third arch the inner part of the recess is narrowed to form the tubal region and the inner part of the second arch is excluded from this portion of the floor. The outer part of the recess is subsequently developed into the tympanic cavity,

FIG. 160.—Left auriculæ of human embryos estimated to be thirty-five and thirty-eight days old respectively. (After His.)

and the floor of this part forms the outer wall of the tympanic cavity up to about the level of the chorda tympani nerve. From this it will be seen that the outer wall of the tympanic cavity 'has both first and second arch elements in it, the share taken by the first arch being limited to the part in front of the handle of the malleus. The area of the second arch includes the outer wall behind this, and turns on to the back wall to take in the tympanohyal region.' During the sixth or seventh month the tympanic antrum appears as an upward and backward expansion of the tympanic cavity.

With regard to the exact mode of development of the ossicles of the middle ear there is some difference of opinion. The view generally held is that the *incus*

FIG. 161.—Auricula in a more advanced stage of development than those represented in fig. 160.

and *malleus* are developed from the dorsal end of the mandibular (Meckel's) cartilage (fig. 116) and the *stapes* from the dorsal median portion of the second arch. The malleus, with the exception of its anterior process, is ossified from a single centre which appears near the neck of the bone; the anterior process is ossified separately in membrane and joins the main part of the bone about the sixth month of foetal life. The incus is ossified from one centre which appears in the upper part of its long crus and ultimately extends into its lenticular process. The stapes first appears as a ring (annulus stapedis) encircling a small vessel, the stapedia artery, which subsequently undergoes atrophy; the stapes is ossified from a single centre which appears in its base.

The external acoustic meatus is developed from the first branchial or outer pharyngeal groove. The lower part of this groove extends inwards as a funnel-shaped tube (primary meatus) from which the cartilaginous portion and a small part of the roof of the osseous portion of the meatus are developed. From the lower part of the funnel-shaped tube an epithelial lamina (*meatal plate*) extends downwards and inwards along the floor of the tubotympanic recess; by the splitting of this lamina the inner part of the meatus (secondary meatus) is produced, while the inner portion of the lamina forms the cutaneous stratum of the tympanic membrane. The

fibrous stratum of the tympanic membrane is formed from the mesoderm which extends between the meatal plate and the entoderm of the floor of the tubotympanic recess.

The auricula or pinna is developed by the gradual differentiation of six tubercles (fig. 159) which appear around the margin of the first branchial groove. Two tubercles appear on the posterior edge of the mandibular arch; these represent the rudiments of the tragus and crus helix. Three are found on the hyoid arch, and indicate, from below upwards, the lobule, antitragus, and antihelix. One arises dorsal to the first branchial groove, and grows downwards behind the antitragus and antihelix; from it and its downward prolongation the upper part of the helix and the cauda helix are developed (figs. 160, 161). Some observers, however, maintain that the lowest tubercle on the hyoid arch becomes the antitragus, and that the lobule is developed later as an independent formation. The rudiment of the *acoustic nerve* appears about the end of the third week as the acoustic ganglion which is closely applied to the cephalic edge of the auditory vesicle. Whether the cells of this ganglion are derived from the ectoderm adjoining the auditory vesicle, or have migrated from the wall of the neural tube, is as yet undetermined. The acoustic ganglion divides into the vestibular ganglion and the spiral ganglion of the cochlea. Their nerve-cells are bipolar, each sending a proximal fibre into the neural tube, and a distal fibre to the epithelial cells of the auditory vesicle.

DEVELOPMENT OF THE VASCULAR SYSTEM

Blood-corpuscles and blood-vessels first make their appearance between the entoderm and the mesoderm of the yolk-sac in what His named the *angioblast*.* Here the cells become arranged into solid strands or cords, and these join to form a close-meshed network, the *area vasculosa*, which covers the entire yolk-sac. The peripheral cells of these strands become flattened and joined to each other by their edges to form the endothelium of the walls of the primitive blood-vessels. Fluid collects within the strands and converts them into tubes, and the more centrally situated cells of the cell-cords are thus pushed to the sides of the vessels and appear as masses of loosely-arranged cells projecting towards the lumen of the tube. These masses are termed *blood-islands* (figs. 162, 163); their cells are detached to form the primary blood-corpuscles (*mesamœboids* of Minot). The earliest blood-vessels, therefore, are formed at several separate centres; from the walls of these vessels buds grow out,

FIG. 162.—Section through the vascular area to show differentiation of primitive vascular cells. (Diagrammatic.)

FIG. 163.—Section through a developing blood-vessel. (Diagrammatic.)

The red and the colourless corpuscles of the blood are all derived from the *mesamœboids*. The earliest blood-corpuscles are thus all nucleated; they are

become vascularised and converted into new vessels, and join with those of neighbouring areas to form a close meshwork. It is uncertain whether the vessels within the body of the embryo are extensions from this network (His) or whether they are of new formation. Most observers agree, however, that, after the aortæ have appeared, no other independent vessels are laid down, i.e. all new vessels are derived from pre-existing ones.

* Recent observations show that blood-islands and blood-vessels appear in the body-stalk and chorion independently of, and previous to, those of the yolk-sac. (Consult an article "On the earliest blood-vessels in Man" by J. L. Bremer in the *Anatomical Record*, vol. viii. Feb. 1914.)

also capable of subdivision and of executing amoeboid movements. Some mesamœboids acquire colouring matter (hæmoglobin); their nuclei disintegrate and are extruded, and the non-nucleated red corpuscles or erythrocytes result. Other mesamœboid cells retain their nuclei; some remain in the blood as the leucocytes; others wander out into the tissues, particularly into the liver, lymphoid tissues, and marrow of the bones, where they form specialised collections from which the corpuscles of the blood are regenerated. From the mesamœboid cells five chief forms are derived: (1) erythrocytes, (2) lymphocytes, (3) finely granular or neutrophil leucocytes, (4) coarsely granular or eosinophil leucocytes, (5) degenerating or basophil leucocytes.

yolk-sac (His), or are developed from vascular cells *in situ*, and subsequently establish connexions with those of the yolk-sac.

The first rudiment of the heart appears in the form of a pair of tubular vessels (primitive aortæ) which are developed in the splanchnopleure of the pericardial area (fig. 164). These two vessels run backwards, one on either side of the notochord,

FIG. 166.—Human embryo about fourteen days old with yolk-sac. (After His.)

and pass into the body-stalk along which they are carried as the umbilical arteries to the chorion.

By the forward growth and flexure of the head the pericardial area and the anterior portions of the primitive aortæ are folded under the head and come to lie on the ventral aspect of the fore-gut, and each vessel now consists of a ventral and a dorsal part united by an arch; these three parts are named respectively the

FIG. 167.—Head of a chick embryo about thirty-eight hours old, viewed from the ventral surface. $\times 26$. (From Duval's Atlas d'Embryologie.)

ventral aorta, the dorsal aorta, and the first aortic arch. The first aortic arches pass through the mandibular arches, and behind them five additional pairs subsequently develop, so that altogether six pairs of aortic arches are formed.

In the pericardial region the two primitive aortæ, which from the first lie close together, come into contact and the partition between them disappears, and thus a single tubular heart is formed (fig. 167); from the cephalic end of the heart the ventral aortæ arise and into its caudal end the umbilical and vitelline veins pour their contents.

FIG. 168.—Diagram to illustrate the simple tubular condition of the heart. From Ecker-Ziegler model.)

FIG. 169.—Heart of a human embryo of about fourteen days. (From a model by His.)

Eternod * described the circulation in a human embryo which measured 1.3 mm. in length and was devoid of mesodermal somites (fig. 165). The rudiment of the heart was situated immediately below the fore-gut and consisted of a short stem. It gave off two vessels, the primitive aortæ, which ran backwards, one on either side of the rudiment of the notochord, and then passed into the body-stalk, along which they were carried to the chorion. From the chorionic villi the blood was returned by a pair of umbilical veins which united in the body-stalk to form a single vein (vena umbilicalis impar); on reaching the embryo this vein divided into two

FIG. 170.—Heart of a human embryo of about fifteen days. (Reconstruction by His.)

which encircled the mouth of the yolk-sac and opened into the heart. At the junction of the yolk-sac and body-stalk each vein was joined by a transitory vitelline vein from the vascular plexus of the yolk-sac.

The transitory vitelline veins are replaced by the true vitelline veins which return the blood from the yolk-sac, and enter the embryo through the anterior wall of the

umbilical orifice (figs. 166, 167). They then traverse the septum transversum, a band of mesoderm which lies between the pericardium and the yolk-sac; in this septum each vitelline vein unites with the corresponding umbilical vein to form the *common vitello-umbilical vein* which opens into the caudal end (sinus venosus) of the tubular heart. The vitello-umbilical veins are soon joined by a pair of anterior cardinal and primitive jugular veins from the head, and a little later each anterior cardinal vein is joined by a posterior cardinal vein from the trunk and limbs and the short trunk (duct of Cuvier) formed by the union of these two veins opens into the corresponding vitello-intestinal vein. The sinus venosus expands in a transverse direction and incorporates the adjoining parts of the vitello-umbilical veins which come to form the right and left horns of the sinus; into either horn of the sinus the three venous trunks, viz. the vitelline vein, the umbilical vein and the duct of Cuvier, open. The liver is developed in the septum transversum, and in the course of its develop-

FIG. 171.—Dorsal surface of the heart of a human embryo of thirty-five days.
(From model by His.)

ment the vitelline and umbilical veins undergo important transformations which will be explained later (page 139).

With the atrophy of the yolk-sac the vitelline circulation diminishes and ultimately ceases, and an increasing amount of blood is carried through the umbilical arteries to the villi of the chorion. Subsequently, as the non-placental chorionic villi atrophy, their vessels disappear; and then the umbilical arteries convey the whole of the blood from the embryo to the placenta, whence it is returned to the embryo by the umbilical veins.

Further development of the Heart.—The simple tubular heart, already described (page 111), elongates and bends so as to form an S-shaped loop, the anterior part convex ventrally and to the right, and the posterior, dorsally and to the left (fig. 169). The intermediate portion arches transversely from left to right, and then turns sharply forward into the anterior part of the loop. Slight constrictions make their appearance in the tube and divide it from behind forwards into five parts, viz.: (1) the *sinus venosus*; (2) the *atrium*; (3) the *ventricle*; (4) the *bulbus cordis*, and (5) the *truncus arteriosus* (fig. 169). The constriction between the atrium and ventricle constitutes the *atrial canal*, and indicates the site of the future atrio-ventricular valves.

The sinus venosus is situated in the septum transversum behind the atrium, and opens into the latter by a median aperture. The sinus is at first placed trans-

versely but soon assumes an oblique position and a crescentic shape (fig. 171); its right half or horn increases in size more rapidly than its left, and the sinus opens into the right portion of the atrium. The right horn of the sinus is ultimately

FIG. 172.—Interior of the dorsal half of the heart of a human embryo of about thirty (From a model by His.)

incorporated with and forms a part of the right atrium, the line of union between it and the auricula being indicated in the interior of the adult atrium by a vertical crest, the *crista terminalis* of His. The left horn, which ultimately receives only the left duct of Cuvier, persists as the coronary sinus (fig. 171). The vitelline and umbilical veins are later replaced by a single vessel, the inferior vena cava, and the

FIG. 173.—Heart showing expansion of the atria. (From Ecker-Ziegler model.)

three veins (inferior vena cava and right and left ducts of Cuvier) open into the dorsal part of the atrium by a common slit-like aperture (fig. 172). The upper part of this aperture represents the opening of the permanent superior vena cava, the lower that of the inferior vena cava, and the intermediate part the orifice of the coronary sinus. The slit-like aperture lies obliquely, and is guarded by two valves,

the *right* and *left venous valves*; above the opening these unite with each other and are continuous with a fold named the *septum spurium*; below the opening they fuse to form a triangular thickening—the *spina vestibuli*. The right venous valve is retained; its cephalic portion, together with the *septum spurium*, forms the *crista terminalis* already mentioned. A small septum, the *sinus septum*, grows from the posterior wall of the sinus venosus to fuse with the right venous valve and divide the rest of it into two parts—an upper, the valve of the inferior vena cava, and a lower, the valve of the coronary sinus. The upper and middle thirds of the left venous valve disappear; the lower third is continued into the *spina vestibuli*, and later fuses with the *septum secundum* of the atria and takes part in the formation of the *limbus fossæ ovalis*.

The atrial canal is at first a short straight tube connecting the atrial with the ventricular portion of the heart, but its growth is relatively slow, and it becomes

FIG. 174.—Interior of the dorsal half of the heart of a human embryo of about thirty-five days. (From a model by His.)

overlapped by the atria and ventricles so that its position on the surface of the heart is indicated only by an annular constriction (fig. 173). Its lumen is reduced to a transverse slit, and two thickenings, or *endocardial cushions* (fig. 172), appear, one on its dorsal, and the other on its ventral wall. These endocardial cushions project into the atrial canal, and, meeting in the middle line, unite to form the *septum intermedium* which divides the canal into two channels, the future right and left atrioventricular orifices.

The atrium grows rapidly, and expanding laterally, partially encircles the *bulbus cordis*; the latter comes to lie in a groove which is the first indication of a division into right and left atria. The cavity of the atrium is divided into right and left chambers by a septum, the *septum primum* (figs. 172, 174), which grows from the dorsal to the ventral wall of the cavity. For a time the atria communicate with each other by an opening, the *ostium primum* of Born, in front of the free margin of the *septum primum*. This opening is closed by the union of the *septum primum* with the *septum intermedium*, but before this occurs a new opening is developed in the upper part of the *septum primum*; this new opening is known as the *foramen ovale* (*ostium secundum* of Born) and persists until birth. A second septum, the *septum secundum* (fig. 175), crescentic in shape, grows from the upper

and dorsal wall of the atrium immediately to the right of the septum primum and foramen ovale. The horns of this crescentic septum secundum fuse with the ventral part of the septum primum, and the intervening free part of the septum

FIG. 175.—Heart of a human embryo of about thirty-five days, opened on right side.
(From a model by His.)

secundum overlaps the foramen ovale and septum primum; the dorsal part of the latter septum acts as a flap-like valve which allows the blood to flow from the right into the left atrium, but not in an opposite direction. After birth, the free edge of the septum secundum blends with the septum primum and the foramen ovale is closed; sometimes the fusion is incomplete and the upper part of the foramen

FIG. 176.—Diagrams to illustrate the transformation of the bulbus cordis. (Keith.)

Ao. Truncus arteriosus. Au. Atrium. B. Bulbus cordis. LV. Left ventricle.
P. Pulmonary artery. RV. Right ventricle.

remains patent. In the adult heart the limbus fossæ ovalis denotes the free margin of the septum secundum.

Issuing from either lung is a pair of pulmonary veins which unite to form a single vein, and these in turn join with one another to form a common trunk which

opens into the left atrium. Subsequently the common trunk and the two veins forming it expand and form the vestibule or greater part of the left atrium, the expansion reaching as far as the orifices of the four veins which open separately into the adult left atrium.

The ventricle is divided by a septum, the *septum inferius* or *ventricular septum* (figs. 172, 174, 175), which grows upwards from the lower part of the ventricle, its position on the surface of the heart being indicated later by the interventricular

FIG. 177.—Diagrams to show the development of the septa of the aortic bulb and ventricles. (Born.)

sulcus. Its dorsal part increases more rapidly than its ventral portion, and fuses with the dorsal part of the septum intermedium. Above its ventral portion there exists for a time an interventricular foramen (fig. 175), but this is ultimately closed by the fusion of the bulbar septum with the ventricular septum.

When the heart assumes its S-shaped form the bulbus cordis lies in front of and ventral to the ventricle. The adjacent walls of the bulbus cordis and ventricle approximate, fuse, and finally disappear, and the bulbus cordis now communicates freely with the right ventricle, while the junction of the bulbus with the truncus arteriosus is brought directly ventral, and applied, to the atrial canal. By the up-growth of the ventricular septum the bulbus cordis is in great measure separated from the left ventricle, but remains an integral part of the right ventricle, of which it forms the infundibulum (fig. 176).

The truncus arteriosus and bulbus cordis are divided by a septum (fig. 177) which makes its appearance in three portions. (1) Two distal ridge-like thickenings project into the lumen of the tube; these increase in size, and ultimately meet and fuse

FIG. 178.—Transverse sections through the aortic bulb to show the growth of the aortic septum. The lowest section is on the left, the highest on the right of the figure. (After His.)

to form the aortic septum, which takes a spiral course towards the proximal end of the truncus arteriosus. It divides the distal part of the truncus into two vessels, the aorta and pulmonary artery, which lie side by side above, but near the heart, the pulmonary artery is in front of the aorta. (2) Four endocardial cushions appear in the proximal part of the truncus arteriosus in the region of the future semilunar valves; the manner in which these are related to the aortic septum is described below. (3) Two endocardial thickenings— anterior and posterior—develop in the bulbus cordis and unite to form a short bulbar septum; this joins above with the aortic septum and below with the ventricular septum. The bulbar septum grows down into the ventricle as an oblique partition, which ultimately

blends with the ventricular septum in such a way as to bring the bulbus cordis into communication with the pulmonary artery, and through the latter with the sixth pair of aortic arches; while the left ventricle is brought into continuity with the aorta, which communicates with the remaining aortic arches. The completed ventricular septum consists of a lower, muscular, and an upper, membranous, part; the former is developed from the septum inferius, the latter from the bulbar septum.

The valves of the heart.—The atrioventricular valves are developed in relation to the atrial canal. By the upward expansion of the bases of the ventricles the canal becomes invaginated into the ventricular cavities. The invaginated margin forms

FIG. 179.—Profile view of a human embryo estimated to be twenty or twenty-one days old. (After His.)

the rudiments of the lateral cusps of the atrioventricular valves; the medial or septal cusps of the valves are developed as downward prolongations of the septum intermedium (fig. 174). The aortic and pulmonary semilunar valves are formed from four endocardial thickenings—an anterior, a posterior, and two lateral—which appear at the proximal end of the truncus arteriosus. As the aortic septum grows downwards it divides each of the lateral thickenings into two, thus giving rise to six thickenings—the rudiments of the semilunar valves—three at the aortic and three at the pulmonary orifice (fig. 178).

Further development of the arteries.—Recent observations show that practically none of the main vessels of the adult arise as single trunks in the embryo. At the site of each vessel a capillary network forms, and by the enlargement of definite paths in this network the larger arteries and veins are developed. The branches of the main arteries are not always simple modifications of the vessels of the capillary network, but may arise as new outgrowths from the enlarged stem.

It has been seen (page 111) that each primitive aorta consists of a ventral and a dorsal part which are continuous through the first aortic arch. The dorsal aortæ at first run backwards separately on either side of the notochord, but in the third week they fuse from about the level of the fourth thoracic to that of the fourth lumbar segment to form a single trunk, the descending aorta. The first aortic arches run through the mandibular arches, and behind them five additional pairs are developed within the corresponding visceral arches; so that, in all, six pairs of aortic arches are formed (figs. 179, 180). The fifth arches are very transitory vessels connecting the truncus arteriosus with the dorsal ends of the sixth arches. The first and second arches pass between the ventral and dorsal aortæ, while the others arise at first by a common stem from the truncus arteriosus, but end separately in the dorsal aortæ. As the neck elongates, the ventral aortæ are drawn out, and the third and fourth arches arise directly from these vessels.

FIG. 180.—Scheme of the aortic arches and their transformations.
(Modified from Kollmann.)

In fishes the aortic arches persist and give off branches to the gills, in which the blood is oxygenated. In mammals some of the arteries remain as permanent structures, while others disappear or are obliterated (fig. 180).

The ventral aortæ.—These persist on both sides. The right ventral aorta forms, as far as the fourth aortic arch, the innominate artery, and beyond that arch the right common and external carotid arteries. The left gives rise to (a) the portion of the aortic arch between the origins of the innominate and left common carotid arteries; (b) the left common and external carotid arteries.

The aortic arches.—The first and second arches disappear, but the dorsal end of the second gives origin to the stapedia artery (fig. 181), a vessel which atrophies in man but persists in some mammals (e.g. the rat).

The stapedia artery passes through the ring of the stapes and divides into supra-orbital, infraorbital, and mandibular branches which follow the three divisions of the trigeminal nerve. The infraorbital and mandibular branches arise from a common stem, the terminal part of which anastomoses with the external carotid. On the obliteration of the stapedia artery this anastomosis enlarges and forms the internal maxillary artery, and the branches of the stapedia artery are now branches of this vessel. The common stem of the infraorbital and mandibular branches passes between the two

roots of the auriculotemporal nerve and becomes the middle meningeal artery; the original supraorbital branch of the stapedia is represented by the orbital twigs of the middle meningeal artery.

The third aortic arch constitutes the commencement of the internal carotid artery, and is therefore named the *carotid arch*. The fourth right arch forms the right subclavian as far as the origin of its internal mammary branch, while the fourth left arch constitutes the arch of the aorta between the origin of the left common

FIG. 181.—Diagram showing the origins of the main branches of the carotid arteries. (Founded on Tandler.) (From Quain's Elements of Anatomy, vol. i., Embryology, T. H. Bryce.)

carotid artery and the termination of the ductus arteriosus. The fifth arch disappears on both sides. The sixth right arch disappears; the sixth left arch gives off the pulmonary arteries and forms the ductus arteriosus; this duct remains pervious during foetal life, but is obliterated a few days after birth and forms the ligamentum arteriosum of the adult. His showed that in the early embryo the sixth arch on either side gives a branch to the corresponding lung, but later both pulmonary arteries take origin from the left arch.

The dorsal aortæ.—In front of the third aortic arches the dorsal aortæ persist and form the continuations of the internal carotid arteries; these arteries pass to the brain, and each divides into an anterior and a posterior branch, the former giving off the ophthalmic and the anterior and middle cerebral arteries, while the latter turns back and joins the cerebral part of the vertebral artery. Behind the third arch the right dorsal aorta disappears as far as the point where the two dorsal aortæ fuse to form the descending aorta. The part of the left dorsal aorta between the third and fourth arches disappears, while the remainder persists to form the descending

part of the arch of the aorta. A constriction, the *aortic isthmus*, is sometimes seen in the aorta between the origin of the left subclavian and the attachment of the ductus arteriosus.

Sometimes the right subclavian artery arises from the aortic arch distal to the origin of the left subclavian and passes upwards and to the right behind the trachea and œsophagus. This condition may be explained by the persistence of the right dorsal aorta and the obliteration of the fourth right arch.

In birds the fourth right arch forms the arch of the aorta; in reptiles the fourth arch persists on both sides and gives rise to the double aortic arch in these animals.

The heart originally lies on the ventral aspect of the pharynx, immediately caudal the stomodæum; with the elongation of the neck and the development of the lungs it recedes within the thorax, and, as a consequence, the anterior ventral aortæ are drawn out and the original position of the fourth and fifth arches is greatly modified. Thus, on the right side the fourth arch recedes to the root of the neck, while on the left side it is withdrawn within the thorax. The recurrent nerves originally pass to the larynx under the sixth pair of arches, and are therefore pulled backwards with the descent of these structures, so that in the adult the left nerve hooks round the ligamentum arteriosum; owing to the disappearance of the fifth and the sixth right arches the right nerve hooks round that immediately above them, i.e. the commencement of the subclavian artery.

The primitive dorsal aortæ give off ventral, dorsal, and lateral groups of segmental arteries.

The *ventral* segmental arteries, the first to be developed, are originally paired vessels, but, after the fusion of the dorsal aortæ, appear as unpaired trunks; they are distributed to the primitive digestive tube and to the wall of the yolk-sac. Three of them persist and constitute the coeliac, superior mesenteric, and inferior mesenteric arteries of the adult. As the viscera supplied by these three arteries descend into the abdomen, the vessels at the same time wander in a caudal direction; thus, the origin of the coeliac artery is transferred from the level of the seventh cervical to that of the twelfth thoracic segment, the superior mesenteric from the second thoracic to the first lumbar segment, and the inferior mesenteric from the twelfth thoracic to the third lumbar segment.

The *dorsal* segmental arteries are at first distributed to the neural tube, but later give off parietal branches to the body-wall; they persist in the thoracic and lumbar regions as the intercostal and lumbar arteries. From the seventh pair the entire left subclavian artery, the greater part of the right subclavian artery, and the proximal part of the vertebral artery are derived; the main part of the cervical portion of the vertebral artery is developed from a longitudinal anastomosis between the first seven dorsal segmental arteries. The second dorsal segmental arteries run alongside the hypoglossal nerves to the brain and are named the hypoglossal arteries. Each sends forwards a branch which forms the cerebral part of the vertebral artery and anastomoses with the posterior branch of the internal carotid artery; the cerebral portions of the two vertebrals unite on the ventral surface of the pons to form the basilar artery. The hypoglossal arteries atrophy, and then the cervical and cerebral parts of the vertebrals are connected by means of the first pair of segmental arteries.

The *lateral* segmental arteries supply, on either side, the mesonephros or Wolfian body and give branches to the testis (or ovary) and the suprarenal glands. One testicular (or ovarian) artery and three suprarenal arteries persist on either side. The inferior phrenic artery arises as a branch from the first, and the renal artery as a branch from the third suprarenal artery. Additional renal arteries are frequently present and may be looked on as branches of persistent lateral segmental arteries.

Recent observations show that several segmental arteries contribute branches to the upper limb-bud and form in it a free capillary anastomosis. Of these branches only one, viz. that derived from the seventh segmental artery, persists to form the subclavian artery. The subclavian artery is prolonged into the limb under the names of the axillary and brachial arteries, and these together constitute the arterial stem for the upper arm; the direct continuation of this stem in the forearm is the volar interosseous artery. A branch which accompanies the median nerve soon increases in size and forms the main vessel (median artery) of the forearm, while the volar interosseous diminishes. Later the radial and ulnar arteries are developed as branches of the brachial part of the stem and coincidently with their

enlargement the median artery recedes; occasionally it persists as a vessel of some size and accompanies the median nerve into the palm of the hand.

The primary arterial stem for the lower limb is formed by the inferior glutæal (sciatic) artery, which accompanies the sciatic nerve along the posterior aspect of the thigh to the back of the knee, whence it is continued as the peronæal artery. This arrangement persists in reptiles and amphibians. The external iliac artery and its continuation the femoral artery arise later from the common iliac. The femoral passes down the front and medial side of the thigh to the bend of the knee and joins the inferior glutæal artery. It quickly enlarges, and, coincidently with this, the lower part of the inferior glutæal atrophies. The anterior and posterior tibial arteries are branches of the main arterial stem.

Further Development of the Veins.—The principal veins of the embryo may be divided into two groups, visceral and parietal.

FIG. 182.—The liver, and the veins in connexion therewith, of a human embryo, twenty-four or twenty-five days old, as seen from the ventral surface. (After His.)

The *visceral veins* are the two vitelline veins bringing the blood from the yolk-sac, and the two umbilical veins returning the blood from the placenta; these four veins open close together into the sinus venosus.

The vitelline veins run upwards at first in front, and subsequently on either side, of the digestive tube. They unite on the ventral surface of the tube, and beyond this are connected to one another by two anastomotic branches, one on the dorsal and the other on the ventral aspect of the duodenal portion of the intestine, which is thus encircled by two venous rings (fig. 182); into the middle, or dorsal anastomosis the superior mesenteric vein opens. The portions of the veins above the upper ring become interrupted by the developing liver and broken up by it into a plexus of small capillary-like vessels termed *sinusoids* (Minot). The vessels conveying the blood to this plexus are named the *venæ advehentes*, and become the branches of the portal vein; while the vessels draining the plexus into the sinus venosus are termed the *venæ revehentes*, and form the future hepatic veins (figs. 182, 183). After a time the left vena revehens no longer communicates directly with the sinus venosus, but opens into the upper part of the right vena revehens (right hepatic vein). The persistent part of the upper venous ring, above the opening of the superior mesenteric vein, forms the trunk of the portal vein.

The two umbilical veins fuse to form a single trunk, the *vena umbilicalis impar*, in the umbilical cord; this trunk divides within the embryo into the right and left umbilical veins which pass forwards to the sinus venosus in the side walls of the body. Like the vitelline veins, the direct connexion of the umbilical veins with

the sinus venosus becomes interrupted by the developing liver, and the whole of the blood from the yolk-sac and placenta passes through the substance of the liver before it reaches the heart. The right umbilical and right vitelline veins shrivel and disappear ; the left umbilical, on the other hand, enlarges and opens into the upper venous ring of the vitelline veins ; with the atrophy of the yolk-sac the left vitelline vein shrivels and disappears. Finally, a direct branch named the *ductus venosus* is established between the upper venous ring and the right hepatic vein ; the ductus venosus enlarges rapidly and forms a wide channel through which most of the blood, returned from the placenta, is carried direct to the heart without passing through the liver. A small part of the blood from the placenta is, however, conveyed

FIG. 189.—Human embryo with the heart and anterior body wall removed to show the sinus venosus and its tributaries. (After His.) (From Kollmann's *Entwicklungsgeschichte*.)

from the left umbilical vein to the liver through the left vena advehens. The left umbilical vein and the ductus venosus are obliterated after birth, and form respectively the ligamentum teres and ligamentum venosum of the liver.

The parietal veins.—A pair of short transverse veins, named the *ducts of Cuvier*, open, one on either side, into the sinus venosus. Each of these ducts receives an ascending and a descending vein. The ascending veins return the blood from the parietes of the trunk and from the Wolfian bodies, and are called *posterior cardinal veins*. The descending veins return the blood from the head, and are called the *anterior cardinal* (primitive jugular) veins (fig. 184). The blood from the lower limbs is collected by the right and left iliac and hypogastric veins, which, in the earlier stages of development, open into the corresponding right and left posterior cardinal veins; later, a transverse branch (the left common iliac vein) is developed between the lower parts of the posterior cardinal veins (fig. 186), and through this the blood is carried into the right posterior cardinal vein. The portion of the left posterior cardinal vein below the left renal vein atrophies and disappears up to the point of entrance of the left testicular vein; the portion above the left renal vein persists

as the hemiazygos and accessory hemiazygos veins and the lower portion of the left superior intercostal vein. The right posterior cardinal vein, which now receives the blood from both lower extremities, forms a large venous trunk along the posterior abdominal wall; up to the level of the renal veins it forms the lower part of the inferior vena cava. Above the level of the renal veins the right posterior cardinal vein persists as the azygos vein and receives the right intercostal veins, while the hemiazygos and accessory hemiazygos veins are brought into communication with it by the development of transverse branches in front of the vertebral column (figs. 186, 187).

Recent observations support the view that the azygos and hemiazygos veins are formed independently of the posterior cardinal veins, and Sabin* has shown, by dissections of injected pig embryos, that the two sets of veins are present at one and the same time. "The posterior cardinal vein is always farther ventral and farther lateral than the azygos."

FIG. 184.—Scheme of the arrangement of the parietal veins.

FIG. 185.—Scheme showing the early stages of the development of the inferior vena cava.

Inferior vena cava.—The development of the inferior vena cava is associated with the formation of two veins, the *subcardinal veins* (figs. 184, 185). These run obliquely along the mesial surfaces of the Wolffian bodies parallel to the posterior cardinal veins; they communicate with the posterior cardinal veins above and below, and also by a series of transverse branches. The two subcardinals are for a time connected with each other in front of the aorta by cross branches, but these disappear and are replaced by a single transverse channel at the level where the renal veins join the posterior cardinals, and at the same level a cross communication is established on either side between the posterior cardinal and subcardinal (fig. 185). The portion of the right subcardinal behind this cross communication disappears, while that in front (i.e. the prerenal part) forms a connexion with the right hepatic vein, and, rapidly enlarging, receives the blood from the postrenal part of the right posterior cardinal through the cross communication referred to. In this manner a single trunk, the *inferior vena cava* (fig. 187), is formed, and consists of the proximal part of the right hepatic vein, the prerenal part of the right subcardinal vein, the postrenal part of the right posterior cardinal vein, and the cross branch which joins these two veins. The left subcardinal disappears, except the part immediately in front of the renal vein, which is retained as the left suprarenal vein. The testicular (or ovarian) vein opens into the postrenal part of the corresponding posterior cardinal vein. This portion of the right posterior cardinal, as already explained, forms the lower part of the inferior vena cava, so that the right spermatic opens directly into that vessel. The postrenal segment of the left posterior cardinal

* Sabin, F. *The Anatomical Record*, vol. viii. 1914.

disappears, with the exception of the portion between the testicular and renal veins, which is retained as the terminal part of the left testicular vein.

In consequence of the atrophy of the Wolffian bodies the posterior cardinal veins diminish in size; the anterior cardinal veins, on the other hand, become enlarged, owing to the rapid development of the head and brain. They are further augmented

FIG. 186.—Diagram showing the development of the main cross branches between the cardinal veins.

FIG. 187.—Diagram showing the completion of the development of the parietal veins.

by receiving the veins (*subclavian*) from the upper extremities, and so come to form the chief veins of the ducts of Cuvier; these ducts gradually assume an almost vertical position in consequence of the descent of the heart into the thorax. The right and left ducts of Cuvier are originally of the same diameter, and are frequently termed the *right* and *left superior vena cava*. By the development of a transverse branch (the *left innominate vein*) between the two anterior cardinal veins, the blood is carried across from the left to the right anterior cardinal (figs. 186, 187). The

portion of the right anterior cardinal vein between the left innominate and the azygos vein forms the upper part of the superior vena cava of the adult; the lower part of this vessel (i.e. below the entrance of the azygos vein) is formed by the right duct of Cuvier. Below the origin of the transverse branch the left anterior cardinal vein and left duct of Cuvier atrophy, the former constituting the upper part of the left superior intercostal vein, while the latter is represented by the ligament of the left vena cava (vestigial fold of Marshall) and the oblique vein of the left atrium (oblique vein of Marshall) (fig. 187). Both right and left superior venæ cavæ are present in some animals, and are occasionally found in the adult

FIG. 188.—Diagram of the veins of the head of an embryo four weeks old. (After Mall.)

human being. The oblique vein of the left atrium passes downwards across the back of the left atrium to open into the coronary sinus, which, as already indicated, represents the persistent left horn of the sinus venosus.

The anterior cardinal veins drain the blood from the brain, and their proximal parts form the internal jugular veins. The distal

portion of each has been named the vena capitis medialis (fig. 188); it runs on the medial side of the auditory vesicle and cerebral nerve-roots, and the portion of it situated in the neighbourhood of the trigeminal nerve becomes the cavernous sinus. The greater part of the vena capitis medialis is replaced, however, by the vena capitis lateralis (fig. 189), which is developed on the lateral aspect of the cerebral nerves from the trigeminal to the hypoglossal. This vein receives three principal tributaries, viz. the anterior cerebral vein from the eye, fore-brain and mid-brain, the middle cerebral vein from the cerebellum, and the posterior cerebral vein from the lower part of the hind-brain. At this stage, therefore, practically the whole of the blood from the brain is drained into the vena capitis lateralis which leaves the skull in company with the facial nerve and opens into the anterior cardinal vein. The terminal branches of the two anterior cerebral veins anastomose

FIG. 189.—Diagram of the veins of the head of an embryo five weeks old. (After Mall.)

in the middle line and form the superior sagittal sinus (fig. 190). By the backward growth of the cerebral hemispheres this sinus comes to anastomose with the middle and posterior cerebral veins, the latter of which leaves the skull through the jugular foramen; this last anastomosis forms the greater part of the transverse sinus. The vena capitis lateralis atrophies; the middle cerebral vein forms the superior petrosal sinus (fig. 191). The inferior petrosal sinus is a later formation.* The external jugular vein at first drains the region behind the ear (posterior auricular) and enters the anterior cardinal as a lateral tributary. A group of veins from the face and lingual region converge to form a common vein, the linguofacial;† which

* Mall, *American Journal of Anatomy*, vol. iv. 1905.

† Lewis, *American Journal of Anatomy*, vol. ix. 1909.

also terminates in the anterior cardinal vein. Later, cross communications develop between the external jugular and the linguofacial, with the result that the posterior group of facial veins is transferred to the external jugular. The cephalic vein is, for a time, a tributary of the external jugular vein, but is later diverted into the axillary vein.

FIG. 190.—Diagram of the veins of the head at the beginning of the third month. (After Mall.)

In early foetal life the heart is placed directly under the head and is relatively of large size. Later it assumes its position in the thorax, but lies at first in the middle line: towards the end of pregnancy it gradually becomes oblique in direction. The atrial portion is at first larger than the ventricular part, and the two atria communicate freely through the foramen ovale. In consequence of the communication, through the ductus arteriosus, between the pulmonary artery and the aorta, the contents of the right ventricle are mainly carried into the latter vessel instead of to the lungs, and hence the wall of the right ventricle is as thick as that of the left. At the end of foetal life, however, the left ventricle is thicker than the right, a difference which becomes more and more emphasised after birth.

FIG. 191.—Diagram of the veins of the head of an older embryo. (After Mall.)

The foetal circulation and the changes which take place in the circulation after birth are described in the section on Angiology.

The Lymphatic Vessels.—The lymphatic system begins as a series of sacs* at the points of junction of certain of the embryonic veins. These lymph-sacs are developed by the confluence of numerous venous capillaries, which at first lose

* Sabin, *American Journal of Anatomy*, vol. ix. 1909.

their connexions with the venous system, but subsequently, on the formation of the sacs, regain them. The lymphatic system is therefore developmentally an offshoot of the venous system, and the lining walls of its vessels are always endothelial.

In the human embryo the lymph-sacs from which the lymphatic vessels are derived are six in number; two paired, the jugular and the posterior lymph-sacs; and two unpaired, the retroperitoneal and the cisterna chyli. In lower mammals an additional pair, the subclavian, is present, but in the human embryo these are merely extensions of the jugular sacs.

The position of the sacs is as follows: (1) the jugular, the first to appear, at the junction of the subclavian vein with the anterior cardinal; (2) the posterior, at the junction of the iliac vein with the posterior cardinal; (3) the retroperitoneal,

FIG. 192.—Scheme showing the relative positions of the primary lymph-sacs based on the description given by Florence Sabin.*

in the root of the mesentery near the suprarenal glands; (4) the cisterna chyli, opposite the third and fourth lumbar vertebræ (fig. 192). From the lymph-sacs the lymphatic vessels bud out along fixed lines corresponding more or less closely with the course of the embryonic blood-vessels. In the body-wall and in the wall of the intestine,* the deeper plexuses are the first to be developed; by continued growth of these the vessels in the superficial layers are gradually formed. The thoracic duct is probably formed from anastomosing outgrowths from the jugular sac and cisterna chyli. At its connexion with the cisterna chyli it is at first double, but the two vessels soon join.

All the lymph-sacs except the cisterna chyli are, at a later stage, divided up by slender connective tissue bridges and transformed into groups of lymph-glands. The lower portion of the cisterna chyli is similarly converted, but its upper portion remains as the adult cisterna.

DEVELOPMENT OF THE DIGESTIVE AND RESPIRATORY APPARATUS

The Digestive Tube.—As already indicated (p. 56), the primitive digestive tube consists of two parts, viz.: (1) the *fore-gut*, within the cephalic flexure, and dorsal to the heart; and (2) the *hind-gut*, within the caudal flexure (fig. 193).

* Heuer, *American Journal of Anatomy*, vol. ix. 1909.

Between these is the wide opening of the yolk-sac, which is gradually narrowed and reduced to a small foramen leading into the vitelline duct. At first the fore-gut and hind-gut end blindly; the anterior end of the fore-gut is separated from the stomodæum by the buccopharyngeal membrane (fig. 193); the hind-gut ends in the cloaca, which is closed by the cloacal membrane.

The mouth.—The mouth is developed partly from the stomodæum, and partly from the floor of the anterior portion of the fore-gut. By the growth of the head-end of the embryo, and the formation of the cephalic flexure, the pericardial area and the buccopharyngeal membrane come to lie on the ventral surface of the embryo. With the further expansion of the brain, and the forward bulging of the pericardium, the buccopharyngeal membrane is depressed between these two prominences. This depression constitutes the *stomodæum* (fig. 193). It is lined by ectoderm, and is separated from the anterior end of the fore-gut by the buccopharyngeal

FIG. 193.—Human embryo about fifteen days old. The brain and heart are represented from right side; the digestive tube and yolk-sac in median section. (After His.)

membrane, which is formed by the apposition of the stomodæal ectoderm with the fore-gut entoderm; at the end of the third week the membrane disappears, and a communication is established between the mouth and the future pharynx. No trace of the membrane is found in the adult; and the communication just mentioned must not be confused with the permanent isthmus faucium. The lips, teeth, and gums are formed from the walls of the stomodæum, but the tongue is developed in the floor of the mouth and pharynx.

The visceral arches grow in a ventral direction and lie between the stomodæum and the pericardium; with the completion of the mandibular arch and the formation of the maxillary processes, the mouth assumes the appearance of a pentagonal orifice, bounded in front by the frontonasal process, behind by the mandibular arch, and laterally by the maxillary processes (fig. 194). With the inward growth and fusion of the palatine processes (figs. 123, 124), the stomodæum is divided into an upper nasal and a lower buccal part. Along the free margins of the processes bounding the mouth cavity a shallow groove appears; this is termed the *primary labial groove*, and from the bottom of it a downgrowth of ectoderm into the underlying mesoderm takes place. Owing to the degeneration of the central cells of this ectodermal downgrowth the groove is deepened and a *secondary labial groove* is

formed, and separates the lips and cheeks from the alveolar processes of the maxillæ and mandible.

The **salivary glands** arise as buds from the epithelial lining of the mouth; the parotid appears during the fourth week in the angle between the maxillary process and the mandibular arch; the submaxillary appears in the sixth week, and the sublingual during the ninth week, in the hollow between the tongue and the mandibular arch.

FIG. 194.—Head end of a human embryo of about thirty to thirty-one days. (From model by Peter.)

The tongue (figs. 195 to 197).

—The tongue consists of an anterior or buccal and a posterior or pharyngeal part. During the third week there appears, immediately behind the ventral ends of the two halves of the mandibular arch, a rounded swelling named the *tuberculum impar*, which was described by His as undergoing enlargement to form the buccal part of the tongue. More recent researches, however, show that this part of the tongue is mainly, if not entirely, developed from a pair of lateral swellings which rise from the inner surface of the mandibular arch and meet in the middle line. The tuberculum impar is said to form the central part of the tongue immediately in front of the foramen cæcum, but Hammar insists that it is purely a transitory structure and forms no

part of the adult tongue. From the ventral ends of the fourth arch there arises a second and larger elevation, in the centre of which is a median groove or furrow. This elevation was named by His the *furcula*, and is at first separated from the tuberculum impar by a depression, but later by a ridge, the *copula*, formed by the forward growth and fusion of the ventral ends of the second and third arches. The posterior or pharyngeal part of the tongue is developed from the copula, which

FIG. 195.—Floor of the pharynx of a human embryo about twenty-six days old. (From model by Peter.)

FIG. 196.—Floor of the pharynx of a human embryo of about the end of the fourth week. (From model by Peter.)

extends forwards in the form of a V, so as to embrace between its two limbs the buccal part of the tongue. At the apex of the V a pit-like invagination occurs, to form the thyroid gland, and this depression is represented in the adult by the *foramen cæcum*. In the adult the union of the anterior and

posterior parts of the tongue is marked by the V-shaped sulcus terminalis, the apex of which is at the foramen cæcum, while the two limbs run lateralwards and forwards parallel to but a little behind the papillæ vallatæ.

The **thyroid gland** is developed from a median diverticulum (fig. 196), which appears about the fourth week on the summit of the tuberculum impar, but later is found in the furrow immediately behind the tuberculum (fig. 195). It grows downwards and backwards as a tubular duct, which bifurcates and subsequently divides into a series of cellular cords, from which the isthmus and lateral lobes of the thyroid gland are developed. As already stated (p. 79), the ultimobranchial bodies from the fifth pharyngeal pouches are enveloped by the lateral lobes of the thyroid gland, but they undergo atrophy and do not form true thyroid tissue. The connexion of the diverticulum with the pharynx is termed the *thyreoglossal duct*; its continuity is subsequently interrupted, and it undergoes obliteration, its upper end being represented by the foramen cæcum of the tongue, and its lower by the pyramidal lobe of the thyroid gland.

The **palatine tonsils** are developed from the dorsal angles of the second pharyngeal pouches. The entoderm which lines these pouches grows in the form of a number of solid buds into the surrounding mesoderm. These buds are excavated by the degeneration and casting off of their central cells, and by this means the tonsillar crypts are formed. Lymphoid cells accumulate around the crypts, and are grouped to form the lymphoid follicles; the latter, however, are not well defined until after birth.

FIG. 198.—Scheme showing the development of branchial epithelial bodies. (Modified from Kohn.)

I, II, III, IV. Pharyngeal pouches.

which become surrounded and isolated by the invading mesoderm. In the latter, numerous lymphoid cells make their appearance, and are aggregated to form lymphoid follicles. These lymphoid cells are probably derivatives of the entodermal cells which lined the original diverticula and their subdivisions. Additional portions of thymus tissue are sometimes developed from the fourth branchial pouches. The thymus continues to grow until the time of puberty and then begins to atrophy.

The two pairs of **parathyroid bodies** are developed as outgrowths from the third and fourth branchial pouches (fig. 198); the diverticula from the third pouches migrate to a lower level than those from the fourth pouches, and consequently the inferior pair of parathyroids is derived from the third, and the superior pair from the fourth, pharyngeal pouches.

FIG. 197.—Floor of the pharynx of a human embryo of about thirty days old. (From model by Peter.)

Two diverticula arise from the fifth pharyngeal pouches and form what are termed the *ultimobranchial bodies* (fig. 198): these fuse with the thyroid gland, but do not form true thyroid tissue.

The hypophysis cerebri.—In the adult the hypophysis cerebri consists of an anterior and a posterior lobe: the former is derived from the ectoderm of the stomodæum, the latter from the floor of the fore-brain. Previous to the rupture of the buccopharyngeal membrane a pouch-like diverticulum of the ectodermal

In B it is in the process of disappearing, and the stomodæum now communicates with the primitive pharynx. *am.* Amnion. *c.* Fore-brain. *ch.* Notochord. *f.* Anterior extremity of fore-gut. *h.* Heart. *if.* Infundibulum. *m.* Wall of brain cavity. *mc.* Mid-brain. *mo.* Hind-brain. *p.* Original position of hypophysial diverticulum. *py.* *ph.* Pharynx. *sp.e.* Speno-ethmoidal; *bc.* Central, and *sp.o.* Speno-occipital parts of basis cranii. *tha.* Thalamus.

lining of the roof of the stomodæum appears. This diverticulum (*pouch of Rathke*) (figs. 199, 200) is the rudiment of the anterior lobe of the hypophysis; it extends upwards in front of the cephalic end of the notochord and in front of the buccopharyngeal membrane, and comes into contact with the under surface* of the fore-brain. It is then constricted off to form a closed vesicle, but remains for a time connected to the ectoderm of the stomodæum by a solid cord of cells. Masses of epithelial cells form on either side and in the front wall of the vesicle, and by the growth of a stroma from the mesoderm between the masses the development of the anterior lobe is completed. A canal (*craniopharyngeal canal*) sometimes opens from the anterior part of the fossa hypophyseos of the sphenoidal bone on to the under surface of the skull, and marks the original position of Rathke's pouch; while at the junction of the septum of the nose with the palate traces of the stomodæal end of the

pouch are occasionally present. (Frazer.) The upwardly directed hypophysial involution becomes applied to the anterolateral aspect of a downwardly directed diverticulum from the base of the fore-brain (p. 95). This diverticulum constitutes the future infundibulum of the floor of the third ventricle, and its inferior extremity is modified to form the posterior lobe of the hypophysis. In some of the lower animals the posterior lobe contains nerve-cells and nerve-fibres, but in man and the higher vertebrates these are replaced by connective tissue.

A small entodermal diverticulum, termed *Seessel's pouch*, projects towards the brain from the anterior end of the fore-gut, close to the buccopharyngeal membrane. The fate and significance of this pouch have not yet been determined.

Further Development of the Digestive Tube.—The upper part of the fore-gut dilates to form the pharynx (fig. 193) in the lateral walls of which the branchial arches are developed (see page 77); the succeeding part remains tubular, and is

elongated to form the œsophagus. About the fourth week a fusiform dilatation, the future stomach, makes its appearance, and beyond this the gut opens into the

FIG. 200.—Sketches in profile of two stages in the development of the human digestive tube. (His.) Fig. A $\times 30$. Fig. B $\times 20$.

yolk-sac (figs. 200, 201); this opening is at first wide, but is gradually narrowed into a tubular stalk, the *yolk-stalk* or *vitelline duct*. Between the stomach and the mouth of the yolk-sac the liver diverticulum appears. From the stomach to the

rectum the alimentary canal is attached to the notochord by a band of mesoderm, from which the common mesentery of the gut is subsequently developed. The stomach is also attached to the anterior abdominal wall as far as the umbilicus

FIG. 201.—Front view of two successive stages in the development of the digestive tube. (His.)

by the septum transversum. The cephalic portion of the septum takes part in the formation of the Diaphragm, while the caudal portion into which the liver grows forms the *ventral mesogastrium* (fig. 202). The stomach undergoes a further dilatation, and its two curvatures can be recognised (figs. 200, B, and 201), the greater directed towards the vertebral column and the lesser towards the anterior wall of the abdomen, while its two surfaces look to the right and left respectively. Distal to

FIG. 202.—The primitive mesentery of a six weeks' human embryo, half schematic. (Kollmann.)

the stomach the gut undergoes great elongation, and forms a V-shaped loop which projects downwards and forwards; from the bend or angle of the loop the vitelline duct opens (fig. 202). For a time a large part of the loop extends beyond the abdominal cavity into the umbilical cord, but by the end of the third month it is

withdrawn within the cavity. With the lengthening of the tube, the mesoderm, which attaches it to the future vertebral column and carries the blood vessels for the supply of the gut, is thinned and drawn out to form the *posterior common mesentery*. The portion of this mesentery attached to the greater curvature of the stomach is named the *dorsal mesogastrium*, and the part which suspends the colon is termed the *mesocolon* (fig. 203). About the sixth week a diverticulum of the gut appears just behind the opening of the vitelline duct, and is differentiated into the future cæcum and vermiform process. The part of the loop on the distal side of the cæcal diverticulum increases in diameter and forms the future ascending and transverse portions of the large intestine. Until the fifth month the cæcal diverticulum has a uniform calibre, but from this time onwards its caudal part remains rudimentary and forms the vermiform process, while its cephalic part expands to form the cæcum. Changes also take place in the shape and position of the stomach. The fundus

FIG. 203.—Abdominal part of digestive tube and its attachment to the primitive or common mesentery. Human embryo of six weeks. (After Toldt.) (From Kollmann's *Entwicklungsgeschichte*.)

is developed as a localised outgrowth or diverticulum from the cardiac end of the greater curvature (Keith and Wood Jones*). F. T. Lewis† points out that in a 16 mm. embryo a canal (gastric canal) passes along the lesser curvature of the stomach from the oesophagus to the pars pylorica, and that in a 44.3 mm. embryo this canal is more distinct than in the earlier stages and reaches from the antrum cardiacum to the incisura angularis.

The dorsal part or greater curvature of the stomach, to which the dorsal mesogastrium is attached, grows much more rapidly than its ventral part or lesser curvature, to which the ventral mesogastrium is fixed. The greater curvature is also carried downwards and to the left, and the right surface of the stomach is now directed backwards, and the left surface forwards (fig. 205)—a change in position which explains why the left vagus nerve is found on the front, and the right vagus on the back of the stomach. The dorsal mesogastrium being attached to the greater curvature necessarily follows its movements, and hence it is greatly elongated and drawn lateralwards and ventralwards from the vertebral column,

* *Proceedings of the Anatomical Society of Great Britain and Ireland*, November 1901.

† *American Journal of Anatomy*, vol. xiii. 1912.

and, as in the case of the stomach, the right surfaces of both the dorsal and ventral mesogastria are now directed backwards, and the left forwards. In this way a pouch, the *bursa omentalis*, is formed behind the stomach, and this increases in size as the digestive tube undergoes further development; the entrance to the pouch constitutes the future *epiploic foramen* (foramen of Winslow). The duodenum is developed from that part of the tube which immediately succeeds the stomach; it undergoes little elongation, being more or less fixed in position by the liver and pancreas, which arise as diverticula from it; for a time its lumen is occluded by an epithelial plug. The duodenum is at first suspended by a mesentery, and projects

FIG. 204.—Reconstruction of a human embryo of 17 mm. (After Mall.) (From Quain's Elements of Anatomy, vol. i., Embryology.)

forwards in the form of a loop; but the loop and its mesentery are subsequently displaced by the transverse colon, so that the right surface of the duodenal mesentery is directed backwards, and, adhering to the parietal peritoneum, is lost. The remainder of the digestive tube elongates greatly, and is thrown into coils, and this elongation demands a corresponding increase in the width of the intestinal attachment of the mesentery, which becomes folded.

At this stage the small and large intestines are attached to the vertebral column by a common mesentery, the coils of the small intestine falling to the right of the middle line, while the large intestine lies on the left side.*

* Sometimes this condition persists throughout life, and the duodenum lies entirely on the right side of the median plane, where it is continued into the jejunum; the arteries to the small intestine (jejunal and ileal) arise from the right instead of the left side of the superior mesenteric artery.

The gut is now rotated upon itself, so that the large intestine is carried over in front of the small intestine, and the cæcum is placed immediately below the liver ;

FIG. 205.—Diagrams to illustrate two stages in the development of the digestive tube and its mesentery. The arrow indicates the entrance to the bursa omentalis.

FIG. 206.—Final disposition of the intestines and their vascular relations. (Jonnesco.)

FIG. 207.—Schematic figure of the bursa omentalis, &c. Human embryo of eight weeks. (Kollmann.)

about the sixth month the cæcum descends into the right iliac fossa, and the large intestine forms an arch consisting of the ascending, transverse, and descending

portions of the colon—the transverse portion crossing in front of the duodenum and lying just below the greater curvature of the stomach; within this arch the coils of the small intestine are disposed (fig. 206). Sometimes the downward progress of the cæcum is arrested, so that in the adult it may be found lying immediately below the liver instead of in the right iliac region.*

FIG. 208.—Diagrams to illustrate the development of the greater omentum and transverse mesocolon.

Further changes take place in the bursa omentalis and in the common mesentery, and give rise to the peritoneal relations seen in the adult. The bursa omentalis, which at first reaches only as far as the greater curvature of the stomach, grows downwards and in front of the transverse colon and the coils of the small intestine to form the greater omentum (fig. 207). Before the pleuroperitoneal opening is closed, the bursa omentalis sends a diverticulum upwards on

FIG. 209.—Tail end of a human embryo from fifteen to eighteen days old. (From model by Keibel.)

FIG. 210.—Cloaca of a human embryo from twenty-five to twenty-seven days old. (From model by Keibel.)

either side of the œsophagus; the left diverticulum soon disappears, but the right is constricted off and forms the *bursa infracardiaca* which may persist in the adult as a small sac lying within the thorax on the right side of the lower end of the œsophagus. The anterior layer of the transverse mesocolon is at first distinct from the posterior layer of the greater omentum, but the two layers blend, and then the greater omentum appears as if attached to the transverse colon (fig. 208). The

*See article by J. Ernest Frazer and R. H. Robbins 'On the factors concerned in causing rotation of the intestine in man,' *Journal of Anatomy and Physiology*, vol. L.

mesenteries of the ascending and descending parts of the colon disappear in the majority of cases, while that of the small intestine assumes the oblique attachment characteristic of its adult condition.

The lesser omentum is formed, as indicated above, by a thinning of the mesoderm (*ventral mesogastrium*) which attaches the stomach and duodenum to the anterior abdominal wall. By the subsequent growth of the liver this leaf of mesoderm is divided into two parts, viz. the lesser omentum between the stomach and liver, and the falciform and coronary ligaments between the liver and the abdominal wall and Diaphragm (fig. 207).

The Rectum and Anal Canal.—The hind-gut is at first prolonged backwards into the body-stalk as the tube of the allantois; but, with the growth and flexure of the tail-end of the embryo, the body-stalk, with its contained allantoic tube, is carried forwards to the ventral aspect of the body, and consequently a bend is formed at the junction of the hind-gut and allantois. This bend dilates to form a pouch, which constitutes the *entodermal cloaca*; into its dorsal part the hind-gut opens, and from its ventral part the allantois passes into the body-stalk. At a later stage the Wolffian and Müllerian ducts open into the ventral portion of the cloaca. The cloaca is, for a time, shut off from the exterior by the *cloacal membrane* which is formed by the apposition of a thick ectodermal and a thin entodermal layer, and reaches at first as far forwards as the future umbilicus. Behind the umbilicus, however, the mesoderm subsequently extends to form the symphysis pubis and the lower part of the abdominal wall. By the growth of the surrounding tissues the cloacal membrane comes to lie at the bottom of a depression, which is lined by ectoderm and named the *ectodermal cloaca* (fig. 209).

The entodermal cloaca is divided into a narrow dorsal and a wide ventral part by means of a partition, the *urorectal septum* (fig. 210), which grows downwards from the ridge separating the allantoic from the cloacal opening of the intestine and ultimately fuses with the cloacal membrane and divides it into an anal and a urogenital membrane. The dorsal part of the cloaca forms the rectum, and the anterior part the urogenital sinus and bladder. For a time a communication named the *cloacal duct* exists between the two parts of the cloaca below the urorectal septum; this duct occasionally persists as a passage between the rectum and the bladder or urethra. By the upgrowth of the surrounding parts the anal part of the cloacal membrane comes to lie at the bottom of a depression, the *proctodæum* or *anal pit*. On the absorption and disappearance of this membrane the rectum communicates with the anal canal (fig. 211). A small part of the hind-gut projects backwards beyond the anal membrane; it is named the *post-anal gut* (fig. 209), and usually becomes obliterated and disappears.*

The Liver arises as a diverticulum from the ventral surface of the fore-gut immediately cranial to the opening of the gut into the yolk-sac (figs. 200, 212). This diverticulum is lined by entoderm, and grows upwards and forwards into the septum transversum which is a mass of mesoderm between the vitelline duct and the pericardial cavity; there the diverticulum gives off two solid buds of cells which represent the right and the left lobes of the liver. The solid buds of cells grow into columns or cylinders, termed the *hepatic cylinders*, which branch and anastomose to form a close meshwork. This network invades the vitelline and umbilical veins, and breaks them up into a series of capillary-like vessels termed *sinusoids* (Minot), which ramify in the meshes of the cellular network. By the continued growth and ramification of the hepatic cylinders the mass of the liver

FIG. 211.—Tail end of a human embryo, from eight and a half to nine weeks old. (From model by Keibel.)

* Consult in this connexion the following article: 'A contribution to the morphology of the human urinogenital tract,' by D. Berry Hart, *Journal of Anatomy and Physiology*, vol. xxxv.

is gradually formed. The original diverticulum from the duodenum forms the common bile-duct, and from this the cystic duct and gall-bladder arise as a solid outgrowth which later acquires a lumen. The opening of the common duct is at first in the ventral wall of the duodenum; later, owing to the rotation of the gut

FIG. 212.—Liver with the septum transversum. Human embryo.
(After model and figure by His.)

the opening is carried to the left and then dorsalwards to the position it occupies in the adult.

As the liver undergoes enlargement, both it and the ventral mesogastrium of the fore-gut are gradually differentiated from the septum transversum; and from the under surface of the latter the liver projects downwards into the abdominal cavity. By the growth of the liver the ventral mesogastrium is divided into two parts, of which the anterior forms the falciform and coronary ligaments and the posterior the lesser omentum. About the third month the liver almost fills the abdominal cavity, and its left lobe is nearly as large as its right. From this period

FIG. 213.—Pancreas of a human embryo of five weeks. (Kollmann.)

FIG. 214.—Pancreas of a human embryo at end of sixth week. (Kollmann.)

the relative development of the liver is less active, more especially that of the left lobe, which actually undergoes some degeneration and becomes smaller than the right; but up to the end of foetal life the liver remains relatively larger than in the adult.

The Pancreas (figs. 213, 214).—The pancreas is developed in two parts, a dorsal and a ventral. The former arises as a diverticulum from the dorsal wall of the duodenum a short distance above the hepatic diverticulum, and, growing upwards and backwards into the dorsal mesogastrium, forms the whole of the body and tail of the pancreas and a part of the head and uncinæ process. The ventral part appears in the form of a diverticulum from the primitive bile-duct at the spot where the latter opens into the duodenum; from the ventral pancreas the remainder

FIG. 215.—Schematic and enlarged transverse section through the body of a human embryo, in the region of the mesogastrium. Beginning of third month. (Toldt.)

of the head and uncinæ process of the pancreas are developed. The duct of the dorsal part (accessory pancreatic duct) therefore opens into the duodenum, while that of the ventral part (pancreatic duct) opens with the common bile-duct. About the sixth week the two parts of the pancreas meet and fuse, and a communication is established between their ducts. After this has occurred the terminal part of the accessory duct, i.e. the part between the duodenum and the point of meeting of the two ducts, undergoes little or no enlargement, while the duct of the ventral part increases in size and forms the main duct of the gland. The opening of the accessory duct into the duodenum is sometimes obliterated, and even when it remains patent it is probable that the whole of the pancreatic secretion is conveyed through the pancreatic duct.

At first the pancreas is directed upwards and backwards between the two layers of the dorsal mesogastrium, which give to it a complete peritoneal investment,

FIG. 216.—Transverse section through same region as in fig. 215, at end of third month. (Toldt.)

and its surfaces look to the right and left. With the change in the position of the stomach the dorsal mesogastrium is drawn downwards and to the left, and the right side of the pancreas is directed backwards, and the left forwards (fig. 215). The right surface becomes applied to the posterior abdominal wall, and the peritoneum which covers it undergoes absorption (fig. 216); and thus, in the adult, the gland appears to lie behind the peritoneal cavity.

The Spleen (fig. 208).—Although the spleen belongs to the group of ductless glands, its development may be conveniently referred to here. It appears about the fifth week as a localised thickening of the mesoderm in the dorsal mesogastrium above the tail of the pancreas. With the change in position of the stomach the

spleen is carried to the left, and comes to lie behind the stomach and in contact with the left kidney. The part of the dorsal mesogastrium which intervened between the spleen and the greater curvature of the stomach forms the gastrolial ligament.

The Respiratory Organs.—The rudiment of the respiratory organs appears as a median *laryngotracheal groove* in the ventral wall of the pharynx. The groove deepens and its lips fuse to form a septum which grows from below upwards and converts the groove into a tube, the *laryngotracheal tube* (fig. 217), the cephalic end of which opens into the pharynx by a slit-like aperture formed by the persistent anterior part of the groove. The tube is lined by entoderm, and from this the epithelial lining of the respiratory tract is developed. The cephalic part of the tube forms the larynx, and its next succeeding part the trachea, while from its caudal end two lateral outgrowths, the right and left *lung buds*, arise, and from them the bronchi and lungs are developed. The first rudiment of the larynx consists of two *arytænoid swellings*, which appear, one on either side of the cephalic end of the

FIG. 217.—The head and neck of a human embryo thirty-two days old, seen from the ventral surface. The floor of the mouth and pharynx have been removed. (His.)

laryngotracheal groove, and are continuous in front of the groove with a transverse ridge (*furcula* of His) which lies between the ventral ends of the third branchial arches and from which the epiglottis is subsequently developed (figs. 196, 197). After the separation of the trachea from the oesophagus, the arytænoid swellings come into contact with one another and with the back of the epiglottis, and the entrance to the larynx assumes the form of a T-shaped cleft, the margins of the cleft adhere to one another and the laryngeal entrance is for a time occluded. The arytænoid swellings are differentiated into the arytænoid and corniculate cartilages, and the folds joining them to the epiglottis form the aryepiglottic folds in which the cuneiform cartilages are developed as derivatives of the epiglottis. The thyreoid cartilage is developed from the ventral ends of the cartilages of the fourth and fifth branchial arches; it appears as two lateral plates, each chondrified from two centres and united in the mid-ventral line by membrane in which an additional centre of chondrification develops.* The cricoid cartilage arises from two cartilaginous centres, which soon unite ventrally and gradually extend and ultimately fuse on the dorsal aspect of the tube.*

According to J. Ernest Frazer,† who has made an important investigation on the development of the larynx, the glottis or space between the vocal folds is the primary opening of the larynx. During the second and third months a lateral mass (arytænoid swelling), derived from the fourth and fifth arches, grows forward on either side

* See footnotes on p. 78.

† *Journal of Anatomy and Physiology*, vol. xlv:

of the primary opening, and from these masses the lateral walls of the vestibule of the larynx are developed. A third elevation or 'central mass' is formed behind the second and third arches. These three masses bound the secondary opening of the larynx. In the lateral masses the arytenoid cartilages and aryepiglottic folds are developed; from the central mass the epiglottis is formed.

The right and left lung buds grow out behind the ducts of Cuvier, and divide into lobules, three appearing on the right, and two on the left, lung-bud; these subdivisions are the early indications of the corresponding lobes of the lungs (figs. 218, 219). The buds undergo further subdivision and ramification, and ultimately

FIG. 218.—Lung buds from a human embryo of about four weeks, showing commencing lobulation. (His.)

FIG. 219.—Lungs of a human embryo more advanced in development. (His.)

end in minute expanded extremities—the infundibula of the lung. After the sixth month the air-sacs begin to make their appearance on the infundibula in the form of minute pouches. The pulmonary arteries are derived from the sixth aortic arches. During the course of their development the lungs migrate in a caudal direction, so that by the time of birth the bifurcation of the trachea is opposite the fourth thoracic vertebra. As the lungs grow they project into the pleuro-peritoneal canals or parts of the coelum which will ultimately form the pleural sacs, and the splanchnic mesoderm enveloping the lung rudiment expands on the growing lung and is converted into the pulmonary pleura.

DEVELOPMENT OF THE BODY-CAVITIES

In the human embryo described by Peters the mesoderm outside the embryonic disc is split into two layers enclosing an extra-embryonic coelum; there is no trace of an intra-embryonic coelum. At a later stage four cavities are formed within the embryo, viz. one on either side within the mesoderm of the pericardial area, and one in either lateral mass of the general mesoderm. All these are at first independent of each other and of the extra-embryonic coelum, but later they become continuous. The two cavities in the general mesoderm unite on the ventral aspect of the gut and form the pleuroperitoneal cavity, which is continuous for a time with the remains of the extra-embryonic coelum round the umbilicus; the two cavities in the pericardial area rapidly join to form a single pericardial cavity, and from this two lateral diverticula extend caudalwards to open into the pleuroperitoneal cavity (fig. 220). Between the two latter diverticula is a mass of mesoderm containing the ducts of Cuvier, and this is continuous ventrally with the mesoderm in which the umbilical veins are passing to the sinus venosus. A septum of mesoderm thus extends across the body of the embryo. It is attached in front to the body-wall between the pericardium and umbilicus; behind to the body-wall at the level of the second cervical segment; laterally it is deficient where the pericardial and pleuroperitoneal cavities communicate, while it is perforated in the middle line by the fore-gut. This partition is termed the *septum transversum*, and is at first a bulky plate of tissue; from it the principal part of the Diaphragm is formed. As development proceeds the dorsal end of the *septum transversum* is carried gradually caudalwards, and when it reaches the fourth cervical segment muscular tissue with the phrenic nerve grow into it. It continues to recede, however, until

it reaches the position of the adult Diaphragm on the bodies of the upper lumbar vertebræ. As already described (page 139), the liver buds grow into the septum transversum and undergo development there.

FIG. 220.—Figure obtained by combining several successive sections of a human embryo of about the fourth week. (Kollmann.)

The upper arrow is in the pleuroperitoneal opening, the lower in the pleuropericardial.

The lung buds meantime have grown out from the fore-gut, and project laterally into the forepart of the pleuroperitoneal cavity; the developing stomach and liver are embedded in the septum transversum; caudal to this the intestines project into the back part of the pleuroperitoneal cavity (fig. 204). Owing to the descent of the dorsal end of the septum transversum the lung buds come to lie above the septum, and thus pleural and peritoneal portions of the pleuroperitoneal cavity (still, however, in free communication with one another) may be recognised; the pericardial cavity opens into the pleural part.

FIG. 221.—Upper part of cœlom of human embryo of 6·8 mm. (seen from behind). (From model by Piper.)

The ultimate separation of the pericardial, pleural, and peritoneal cavities from one another is effected by the growth of a ridge of tissue (*pulmonary ridge* of Mall) on either side from the mesoderm surrounding the duct of Cuvier (figs. 220, 221).

DEVELOPMENT OF URINARY AND GENERATIVE ORGANS 145

The front or cephalic part of this ridge (pleuropericardial membrane) grows across and obliterates the pleuropericardial opening; the hinder or caudal part (pleuroperitoneal membrane) grows across the pleuroperitoneal opening.

FIG. 222.—Diagram of transverse section through rabbit embryo. (After Keith.)

With the continued growth of the lungs the pleural cavities are pushed forwards in the body-wall towards the ventral median line, thus separating the pericardium from the lateral thoracic walls (fig. 222). The further development of the peritoneal cavity has been described with the development of the digestive tube (page 132 *et seq.*).

FIG. 223.—The thoracic aspect of the Diaphragm of a newly born child in which the communication between the peritoneum and pleura has not been closed on the left side; the position of the opening is marked on the right side by the spinocostal hiatus. (After Keith.)

DEVELOPMENT OF THE URINARY AND GENERATIVE ORGANS

The urinary and generative organs are developed from the intermediate cell-mass which is situated between the primitive segments and the lateral plates of mesoderm. The permanent organs of the adult are preceded by a set of embryonic structures on either side; these consist of the pronephros, the mesonephros, the metanephros,

and the Wolffian and Müllerian ducts. The pronephros disappears very early; the structural elements of the mesonephros mostly degenerate, but in their place is developed the genital gland in association with which the Wolffian duct remains as the duct of the male genital gland, the Müllerian as that of the female; some of the tubules of the metanephros form part of the permanent kidney.

FIG. 224.—Section of the urogenital fold of a chick embryo of the fourth day. (Waldeyer.)

The Pronephros and Wolffian duct.—In the outer part of the intermediate cell-mass, immediately under the ectoderm, in the region from about the fifth cervical to the third thoracic segment, short evaginations from each segment grow dorsalwards and extend caudalwards, fusing successively from before backwards to form the *pronephric duct*. This duct continues to grow caudalwards until it opens into the ventral part of the cloaca; beyond the pronephros it is termed the *Wolffian duct*.

The original evaginations form a series of transverse tubules each of which communicates by means of a funnel-shaped ciliated opening with the coelomic

FIG. 225.—Enlarged view, from the front, of the left Wolffian body before any distinction of sex has appeared. (From Farre, after Kobelt.)

a, a, b, c, d. Tubular structure of the Wolffian body. *e.* Wolffian duct. *f.* Its upper extremity. *g.* Its termination in *x*, the urogenital sinus. *h.* Müllerian duct. *i.* Its upper, funnel-shaped extremity. *k.* Its lower end, terminating in the urogenital sinus. *l.* The genital gland. *x.* Urogenital sinus.

cavity, and in the course of each duct a glomerulus also is developed. Secondary glomeruli are formed, and the complete group constitutes the *pronephros*. The tubules of the pronephros undergo rapid atrophy and disappear, but the Wolffian duct persists as the duct of the mesonephros.

The Mesonephros, Müllerian duct, and Genital gland.—On the medial side of the Wolffian duct, and extending from the sixth cervical to the third lumbar segment, the *Wolffian tubules* (fig. 224) are developed. Each tubule first appears as

a solid mass of cells, which later becomes hollowed in the centre; one end grows towards and finally opens into the Wolffian duct, the other dilates and is invaginated by a tuft of capillary blood-vessels to form a glomerulus. The tubules collectively constitute the *mesonephros* or *Wolffian body* (figs. 204, 225). By the fifth or sixth

Fig. 226.—Broad ligament of adult, showing epoöphoron.
(From Farro, after Kobelt.)

a, a. week this body forms an elongated spindle-shaped structure, termed the *urogenital fold* (fig. 224), which projects into the coelomic cavity on either side of the dorsal mesentery, reaching from the septum transversum in front to the fifth lumbar segment behind; in these folds the genital glands are developed. The Wolffian bodies persist and form the permanent kidneys in fishes and amphibians, but in reptiles, birds, and mammals they atrophy and for the most part disappear coincidently with the development of the permanent kidneys. The atrophy begins during the sixth or seventh week and proceeds rapidly, so that by the beginning of the fifth month only the ducts and a few of the tubules remain.

In the male the Wolffian duct persists, and forms the tube of the epididymis, the ductus deferens, and the ejaculatory duct; during the third month the seminal vesicle arises as a lateral diverticulum from the hinder end of the duct. A large part of the head end of the mesonephros atrophies and disappears; of the remainder the anterior tubules form the efferent ducts of the testis; while the posterior tubules are represented by the ductuli aberrantes, and by the paradidymis which is sometimes found in front of the spermatic cord above the head of the epididymis (fig. 228, C).

In the female the Wolffian bodies and ducts atrophy. The remains of the Wolffian tubules are represented by the epoöphoron or organ of Rosenmüller, and the paroöphoron, two small collections of rudimentary, blind tubules which are situated in the mesosalpinx (fig. 226). The lower part of the Wolffian duct disappears, while the upper part persists as the longitudinal duct of the epoöphoron or duct of Gärtner* (fig. 228, B).

Fig. 227.—Urogenital sinus of a female human embryo, from eight and a half to nine weeks old. (From model by Keibel.)

* Berry Hart (*op. cit.*) has described the Wolffian ducts as ending at the site of the future hymen in bulbous enlargements, which he has named the *Wolffian bulbs*; and states that the hymen is formed by these bulbs, 'aided by a special involution from below of the cells lining

The Müllerian ducts.—Shortly after the formation of the Wolffian ducts a second pair of ducts is developed; these are named the *Müllerian ducts*. Each arises on the lateral aspect of the corresponding Wolffian duct as a tubular invagination of the cells lining the coelom (fig. 224). The orifice of the invagination remains patent, and undergoes enlargement and modification to form the abdominal ostium of the uterine tube. The ducts pass backwards, and run at first lateral to the Wolffian ducts; towards the posterior end of the embryo they cross to the medial side of the Wolffian ducts, and run side by side between and behind them—the four ducts forming what is termed the *genital cord* (fig. 227). The Müllerian ducts end on the *Müllerian eminence*, an epithelial elevation in the ventral part of the cloaca between the orifices of the Wolffian ducts; at a later date they open into the cloaca in this situation.

In the male the Müllerian ducts atrophy, but traces of their anterior ends are represented by the appendices of the testes (hydatids of Morgagni), while their terminal fused portions form the utricle which opens into the floor of the prostatic portion of the urethra (fig. 228, C).

In the female the Müllerian ducts persist and undergo further development. The portions which lie in the genital cord fuse to form the uterus; the parts in front of this cord remain separate, and each forms the corresponding uterine tube—the abdominal ostium of which is developed from the anterior extremity of the original tubular invagination from the coelom (fig. 228, B). The fusion of the Müllerian ducts begins in the third month, and the septum formed by their fused medial walls disappears from below upwards, and thus the cavity of the uterus is produced. In some animals, and occasionally in the human subject, the septum persists, giving rise to a bicornuate uterus. About the fifth month an annular constriction marks the position of the neck of the uterus, and after the sixth month the walls of the uterus begin to thicken. The vagina is formed from two solid extensions from the ends of the Müllerian ducts; these grow at first as solid cords which push their way towards the urogenital septum. The ends fuse with one another, and by the breaking down of the central cells the cavity of the vagina results, and this cavity opens on the exterior through the urogenital septum; a portion of the septum remains to form the hymen.

Genital glands.—The first appearance of the genital gland is essentially the same in the two sexes, and consists of a thickening of the epithelial layer which lines the coelomic cavity on the medial side of the urogenital fold (fig. 224). The thick plate of epithelium extends deeply, and, pushing the mesoderm before it, forms a distinct projection. This is termed the *genital ridge* (fig. 224), and from it the testis in the male and the ovary in the female are developed. At first the mesonephros and genital ridge are suspended by a common mesentery, but as the embryo grows the genital ridge is gradually pinched off from the mesonephros, with which it is at first continuous, though it still remains connected to the remnant of this body by a fold of peritoneum, the *mesorchium* or *mesovarium* (fig. 229). The distinction of sex in the genital ridge is perceptible about the seventh week.

FIG. 229.—Transverse section of human embryo, from eight and a half to nine weeks old. (From model by Keibel.)

the urogenital sinus. He further believes that 'the lower third of the vagina is due to the coalescence of the upper portion of the urogenital sinus and the lower ends of the Wolffian ducts,' and that 'the epithelial lining of the vagina is derived from the Wolffian bulbs.' He also regards the *colliculus seminalis* of the male urethra as being formed from the lower part of the Wolffian ducts.

In a 10 mm. embryo the genital gland reaches from about the sixth to the twelfth thoracic segment. It subsequently extends as far as the second sacral segment, but simultaneously with this caudal extension the cranial three-fourths of the gland undergo degeneration.

The ovary, formed from the genital ridge, is at first a group of cells derived from the coelomic epithelium; later the group is differentiated into a central mass and a layer of surface epithelium (fig. 230). Between the cells of the surface epithelium a number of larger cells, the *primitive ova*, are found, and these are carried into the subjacent stroma by bud-like ingrowths (*genital cords*) of the surface epithelium (fig. 231). The surface epithelium ultimately forms the permanent epithelial covering of this organ; it loses its connexion with the central mass of cells, and

FIG. 230.—Longitudinal section of ovary of cat embryo, 9.4 cm. long. (Schematic.)
(After Coert, from Hertwig's *Handbuch der Entwicklungslehre*.)

a tunica albuginea develops between them. The ova are chiefly derived from the cells of the central mass; the latter are separated from one another by an irregular growth of connective tissue; each ovum assumes a covering of connective tissue (follicle) cells, and in this way the rudiments of the ovarian follicles are formed (fig. 231).

It was formerly supposed that the primitive germ-cells were derived from the coelomic epithelium covering the genital ridge, but it has been shown that, in the lower vertebrates at least, they are probably formed during the later stages of cell-cleavage. They can be distinguished from the somatic cells by the large size of their bodies and nuclei, and by their cytoplasm which is only faintly granular and has no affinity for ordinary stains, but assumes a brownish colour when treated by osmic acid. These primitive germ-cells migrate first into the root of the mesentery and from there into the coelomic epithelium covering the genital ridge. A considerable number apparently never reach their proper destination, since 'vagrant germ-cells are found in all sorts of places, but more particularly on the mesentery.* Some of these may possibly find their way into the germinal ridge; some probably undergo atrophy, while others may persist and become the seat of dermoid tumours.

* Beard, *Journal of Anatomy and Physiology*, vol. xxxviii,

The testis is developed in much the same way as the ovary. Like the ovary, in its earliest stages it consists of a central mass of epithelium covered by a surface epithelium. In the central mass a series of epithelial cords (testis-cords) appear (fig. 232); simultaneously the peripheral part of the central mass is converted into

FIG. 231.—Section of the ovary of a newly born child. (Waldeyer.)

a tunica albuginea which intervenes between the testis-cords and the surface epithelium and excludes the latter from any part in the formation of the tissue of the testis. The thin inner ends of the testis-cords converge toward the future hilum and there unite in a network which ultimately becomes the rete testis. From the outer parts of the testis-cords the seminiferous tubules are developed, and between them connective tissue septa extend. The tubules of the rete testis become connected with outgrowths from the Wolffian body, which, as already mentioned, form the efferent ducts of the testis.

Descent of the testes.—The testes, at an early period of foetal life, are placed in the posterior part of the abdominal cavity, and each is attached to the mesonephros by a peritoneal fold, named the *mesorchium*. From the front of the mesonephros a fold of peritoneum, termed the *inguinal fold*, grows forwards to meet and fuse with a peritoneal fold, named the *inguinal crest*, which grows backwards from the anterolateral abdominal wall. The testis thus acquires an indirect connexion with the anterior abdominal wall; and at the same time a portion of the peritoneal cavity lateral to these fused folds is marked off as the future saccus vaginalis. In the inguinal crest a peculiar structure, the *gubernaculum testis*, makes its appearance. This is at first a slender band, extending from that part of the skin

FIG. 232.—Section of a genital cord of the testis of a human embryo 3.5 cm. long. (Felix and Bühler.)

which afterwards forms the scrotum, through the inguinal canal to the body and epididymis of the testis. As development advances, the peritoneum enclosing the gubernaculum forms two folds, one above the testis and the other below it. The

one above the testis is the *plica vascularis*, and contains ultimately the testicular vessels. The one below, the *plica gubernatrix*, contains the lower part of the gubernaculum and ends at the abdominal inguinal ring in a tube of peritoneum, the *saccus vaginalis*, which protrudes down the inguinal canal. By the fifth month the upper part of the gubernaculum has disappeared, while the lower part has become a thick cord, and consists of a central core of unstriated muscle-fibres, and outside this of a firm layer of striped elements, connected with the abdominal wall; as the scrotum develops, the main portion of the lower end of the gubernaculum is carried, with the skin to which it is attached, to the bottom of this pouch. The

FIG. 233.—Tail end of human embryo, from twenty-five to twenty-nine days old. (From model by Keibel.)

saccus vaginalis projects itself downwards into the inguinal canal, and emerges at the subcutaneous inguinal ring, pushing before it a part of the *Obliquus internus* and the aponeurosis of the *Obliquus externus*, which form respectively the *Cremaster* muscle and the *intercrural fascia*. It forms a gradually elongating pouch, which eventually reaches the bottom of the scrotum, and behind this pouch the gubernaculum lies. The testis, being attached by the gubernaculum to the bottom of the scrotum, passes first into the inguinal canal and eventually into the scrotum, invaginating the *saccus vaginalis* from behind. It seems certain also that the gubernacular cord becomes shortened

as development proceeds, and this assists in causing the testis to reach the bottom of the scrotum. By the end of the eighth month the testis has reached the scrotum, and the upper part of the *saccus vaginalis* is converted into a narrow canal which is obliterated a short time after birth, and this obliteration extends gradually downwards to within a short distance of the testis. The lower part of the *saccus vaginalis* is thus entirely cut off from the general peritoneal cavity and constitutes the parietal portion of the *tunica vaginalis*. Sometimes the testes are retained within the abdomen or inguinal canal, constituting what is known as *cryptorchismus*.

Descent of the ovaries.—In the female there is also a gubernaculum, which effects a considerable change in the position of the ovary, though not so extensive as that of the testis. The gubernaculum in the female lies in contact with the fundus of the uterus and contracts adhesions to this organ. The part of the gubernaculum between the ovary and the uterus becomes the ligament of the ovary, the part between the uterus and the *labium majus* the round ligament of the uterus; a pouch of peritoneum analogous to the *saccus vaginalis* in the male accompanies it along the inguinal canal; it is called the *canal of Nuck*. In rare cases the gubernaculum may fail to contract adhesions to the uterus, and then the ovary descends through the inguinal canal into the *labium majus*, and under these circumstances its position resembles that of the testis.

FIG. 234.—Tail end of human embryo, from thirty-two to thirty-three days old. (From model by Keibel.)

The Metanephros and the Permanent Kidney.—The rudiments of the permanent kidneys make their appearance about the end of the first or the beginning of the second month. Each kidney has a twofold origin, part arising from the *metanephros*, and part as a diverticulum from the hind-end of the *Wolffian duct* close to where the latter opens into the cloaca (figs. 233, 234). The *metanephros* arises in the intermediate cell mass, caudal to the *mesonephros* which it resembles in

structure. The diverticulum from the Wolffian duct grows dorsalwards and forwards along the posterior abdominal wall, where its blind extremity expands and subsequently divides into several buds, which form the rudiments of the pelvis and calyces of the kidney; by continued growth and subdivision it gives rise to the collecting tubules of the kidney. The proximal portion of the diverticulum becomes the ureter. The secretory tubules are developed from the metanephros, which is moulded over the growing end of the diverticulum from the Wolffian duct. The tubules of the metanephros, unlike those of the pronephros and mesonephros, do not open into the Wolffian duct. One end of each tubule expands to form a glomerulus, while the rest rapidly elongates to form the convoluted tubule, the loop of Henle, and the junctional tubule; the last joins and establishes communication with one of the collecting tubules which are derived from the ultimate ramifications of the diverticulum from the Wolffian duct. The mesoderm around the tubules is condensed to form the connective tissue of the kidney. The ureter opens at first into the hind-end of the Wolffian duct; after the sixth week it separates from the Wolffian duct, and opens independently into the part of the cloaca which ultimately becomes the bladder (figs. 235, 236).

The secretory tubules of the kidney are arranged into pyramidal masses or lobules, the bases of which are at the surface of the kidney, while their apices constitute the renal papillæ. The lobulated condition of the kidneys exists for some time after birth and traces of it may be found in the adult. The kidneys of the ox and many other animals remain lobulated throughout life.

The Urinary Bladder.—The bladder is formed partly from the entodermal cloaca and partly from the ends of the Wolffian ducts; the allantois takes no share in its formation. After the separation of the rectum from the dorsal part of the cloaca (p. 139), the ventral part becomes subdivided into three portions: (1) a dorsal *vesico-urethral portion*, continuous with the allantois—into this portion the Wolffian ducts open; (2) an intermediate narrow channel, the *pelvic portion*; and (3) a ventral, broad *phallic portion*, closed externally by the urogenital membrane (fig. 236). The second and third parts together constitute the *urogenital sinus*. The vesico-urethral portion absorbs the ends of the Wolffian ducts and the associated ends of the renal diverticula, and these give rise to the trigone of the bladder and part of the prostatic urethra. The remainder of the vesico-urethral portion forms the body of the bladder and part of the prostatic urethra; its apex is prolonged to the umbilicus as a narrow canal, which later is obliterated and becomes the medial umbilical ligament (urachus).

The prostate originally consists of two separate portions, each of which arises as a series of buds from the epithelial lining of the urogenital sinus and vesico-urethral part of the cloaca, between the third and fourth months. These buds become tubular, and form the glandular substance of the two lobes which ultimately meet and fuse behind the urethra and also extend on to its ventral aspect. The isthmus or middle lobe is formed as an extension of the lateral lobes between the common ejaculatory ducts and the bladder. *Skene's ducts* in the female urethra are regarded as the homologues of the prostatic glands.

The *bulbo-urethral glands of Cowper* in the male, and *greater vestibular glands of Bartholin* in the female, also arise as diverticula from the epithelial lining of the urogenital sinus.

The External Organs of Generation (fig. 237).—As already stated (p. 139), the cloacal membrane, composed of ectoderm and entoderm, originally reaches from the umbilicus to the tail. The mesoderm extends to the midventral line for some

FIG. 235.—Tail end of human embryo, from eight and a half to nine weeks old. (From model by Keibel.)

distance behind the umbilicus, and forms the lower part of the abdominal wall; it ends below in a prominent swelling, the *cloacal tubercle*. Behind this tubercle the urogenital part of the cloacal membrane separates the ingrowing sheets of mesoderm.

The first rudiment of the penis (or clitoris) is a structure termed the *phallus*; it is derived from the phallic portion of the cloaca which has extended on to the end and sides of the under surface of the cloacal tubercle. The terminal part of the phallus, representing the future glans penis, becomes solid; the remainder, which is hollow, is converted into a longitudinal groove by the absorption of the urogenital membrane.

In the female a deep groove forms around the phallus and separates it from the rest of the cloacal tubercle, which is now termed the *genital tubercle*. The sides of the genital tubercle grow backwards as the *genital swellings*, which ultimately form the labia majora; the tubercle itself becomes the mons pubis. The labia minora arise by the continued growth of the lips of the groove on the under surface of the phallus; the remainder of the phallus forms the clitoris.

FIG. 236.—Primitive kidney and bladder, from a reconstruction. (After Schreiner.)
(From Quain's Elements of Anatomy, vol. i., Embryology.)

In the male the early changes are similar, but the pelvic portion of the cloaca undergoes much greater development, pushing before it the phallic portion. The genital swellings extend round between the pelvic portion and the anus, and form a scrotal area; during the changes associated with the descent of the testes this area is drawn out to form the scrotal sacs. The penis is developed from the phallus. As in the female, the urogenital membrane undergoes absorption, forming a channel on the under surface of the phallus; this channel extends only as far forwards as the corona glandis.

The corpora cavernosa of the penis (or clitoris) and of the urethra arise from the mesodermal tissue in the phallus; they are at first dense structures, but later vascular spaces appear in them, and they gradually become cavernous.

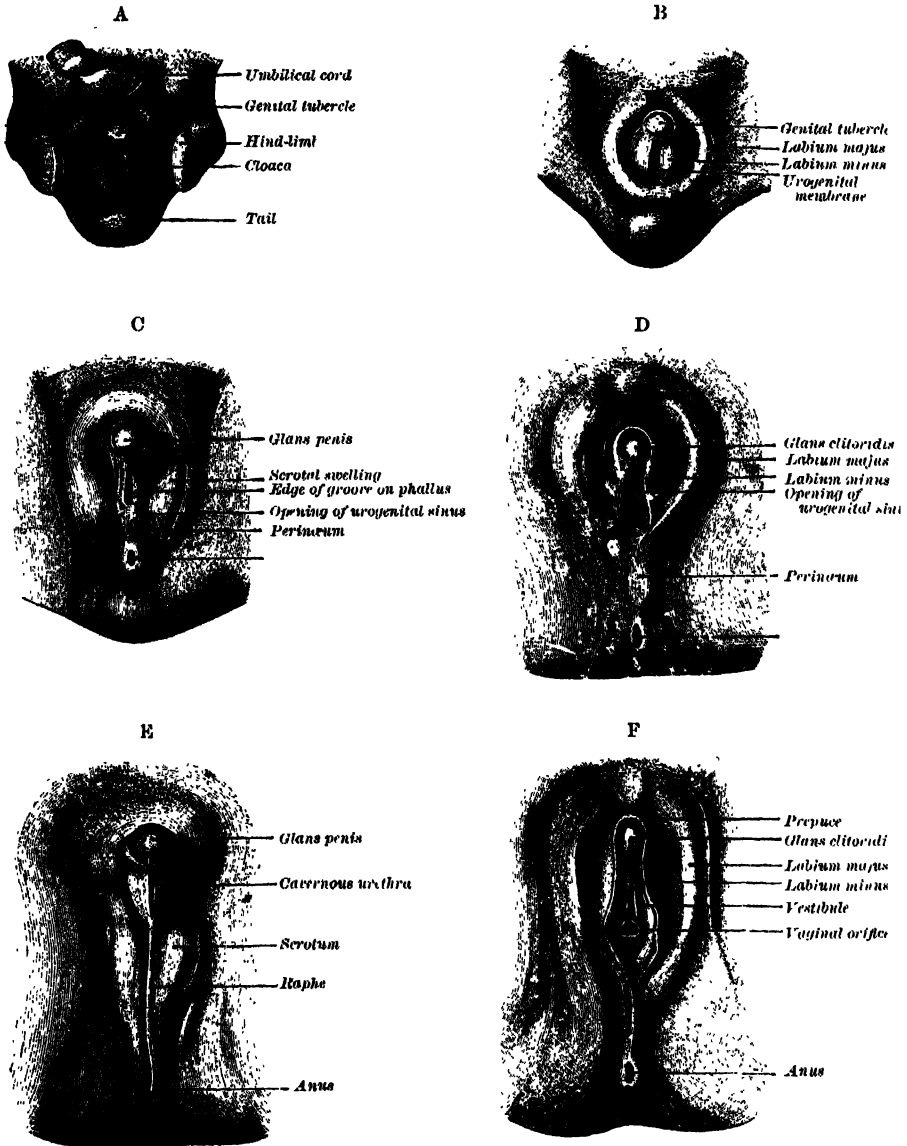

The *prepuce* is formed by the growth of a solid plate of ectoderm into the superficial part of the phallus; on coronal section this plate presents the shape of a horseshoe. By the breaking down of its more centrally situated cells the plate is split into two lamellæ, and a cutaneous fold, the prepuce, is liberated and forms a hood over the glans. 'Adherent prepuce is not an adhesion really, but a hindered central desquamation' (Berry Hart, *op. cit.*).

The Urethra.—As already described, in both sexes the phallic portion of the cloaca extends on to the under surface of the cloacal tubercle as far forwards as the apex. At the apex the walls of the phallic portion come together and fuse, the lumen is obliterated, and a solid plate, the *urethral plate*, is formed. The remainder

of the phallic portion is for a time tubular, and then, by the absorption of the urogenital membrane, it establishes a communication with the exterior; this opening is the *primitive urogenital ostium*, and it extends forwards to the corona glandis.

In the female this condition is largely retained; the portion of the groove on the clitoris broadens out while the body of the clitoris enlarges, and thus the adult urethral opening is situated behind the base of the clitoris.

FIG. 237.—Stages in the development of the external sexual organs in the male and female. (From the Ecker-Ziegler models.)

In the male, by the greater growth of the pelvic portion of the cloaca a longer urethra is formed, and the primitive ostium is carried forwards with the phallus, but it still ends at the corona glandis. Later the groove closes from behind forwards. Meanwhile the urethral plate of the glans breaks down centrally to form a median groove continuous with the primitive ostium. This groove also closes from behind forwards, so that the external urethral opening is shifted forwards to the end of the glans penis.

THE FORM OF THE EMBRYO AT DIFFERENT STAGES OF ITS GROWTH.

First Week.—During the first week the ovum is in the uterine tube. Having been fertilised in the upper part of the tube, it passes slowly down, undergoing segmentation, reaches the uterus. Peters* described a specimen, the age of which he reckoned

FIG. 238.—Human embryo 2.6 mm. long. (His.)

as from three to four days. It was imbedded in the decidua on the posterior wall of the uterus and enveloped by a decidua capsularis, the central part of which, however, consisted merely of a layer of fibrin. The ovum was in the form of a sac, the outer wall of which consisted of a layer of trophoblast; inside this was a thin layer of mesoderm composed of round, oval, and spindle-shaped cells. Numerous villous processes—some consisting of trophoblast only, others possessing a core of mesoderm—

FIG. 239.—Human embryo between eighteen and twenty-one days old. (His.)

projected from the surface of the ovum into the surrounding decidua. Inside this sac the rudiment of the embryo was found in the form of a patch of ectoderm, covered by a small but completely closed amnion. It possessed a minute archenteron and

* Peters, *Die Einbettung des menschlichen Eies*, 1899.

was surrounded by mesoderm, which was connected by a band to that lining the trophoblast (fig. 94).*

Second Week.—By the end of this week the ovum has increased considerably in size, and the majority of its villi are vascularised. The embryo has assumed a definite form, and its cephalic and caudal extremities are easily distinguished. The neural folds are partly united. The embryo is more completely separated from the yolk-sac, and the paraxial mesoderm is being divided into the primitive segments (fig. 238.)

FIG. 240.—Human embryo, between twenty-seven and thirty days old (His.)

Third Week.—By the end of the third week the embryo is strongly curved, and the primitive segments number about thirty. The primary divisions of the brain are visible, and the optic and auditory vesicles are formed. Four branchial grooves are present; the stomodæum is well marked, and the buccopharyngeal membrane has disappeared. The rudiments of the limbs are seen as short buds, and the Wolffian bodies are visible (fig. 239).

FIG. 241.—Human embryo, between thirty-one and thirty-four days old. (His.)

Fourth Week.—The embryo is markedly curved on itself, and when viewed in profile is almost circular in outline. The cerebral hemispheres appear as hollow buds, and the elevations which form the rudiments of the auricula are visible. The limbs now appear as oval flattened projections (fig. 240).

* Bryce and Teacher (*Early Development and Imbedding of the Human Ovum*, 1908) are of opinion that the age of Peters' ovum has been understated.

Fifth Week.—The embryo is less curved and the head is relatively of large size. Differentiation of the limbs into their segments occurs. The nose forms a short, flattened projection. The cloacal tubercle is evident (fig. 241).

Sixth Week.—The curvature of the embryo is further diminished. The branchial grooves—except the first—have disappeared, and the rudiments of the fingers and toes can be recognised (fig. 242).

Seventh and Eighth Weeks.—The flexure of the head is gradually reduced and the neck is somewhat lengthened. The upper lip is completed and the nose is more prominent. The nostrils are directed forwards and the palate is not completely developed. The eyelids are present in the shape of folds above and below the eye, and the different parts of the auricle are distinguishable. By the end of the second month the fœtus measures from 28 to 30 mm. in length (fig. 243).

FIG. 242.—Human embryo about six weeks old. (Hlis.)

Third Month.—The head is extended and the neck is lengthened. The eyelids meet and fuse, remaining closed until the end of the sixth month. The limbs are well developed and nails appear on the digits. The external generative organs are so far differentiated that it is possible to distinguish the sex. By the end of this month the length of the fœtus is about 7 cm., but if the legs be included it is from 9 to 10 cm.

Fourth Month.—The loop of gut which projected into the umbilical cord is withdrawn within the fœtus. The hairs begin to make their appearance. There is a general increase in size, so that by the end of the fourth month the fœtus measures 12 to 13 cm. in length, but if the legs be included it is from 16 to 20 cm.

Fifth Month.—It is during the fifth month that the first movements of the fœtus are usually observed. The eruption of hair on the head commences, and the vernix caseosa begins to be deposited. By the end of this month the total length of the fœtus, including the legs, is from 25 to 27 cm.

Sixth Month.—The body is covered by fine hairs (*lanugo*) and the deposit of vernix caseosa is considerable. The papillæ of the skin are developed and the free borders of the nails project from the corium of the dermis. Measured from vertex to heels, the total length of the fœtus at the end of this month is from 30 to 32 cm.

Seventh Month.—The pupillary membrane atrophies and the eyelids are open. The testis descends with the vaginal sac of the peritoneum. From vertex to heels the total length at the end of the seventh month is from 35 to 36 cm. The weight is about 1·5 kilograms.

Eighth Month.—The skin assumes a pink colour and is now entirely coated with vernix caseosa, and the lanugo begins to disappear. Subcutaneous fat has been developed to a considerable extent, and the foetus presents a plump appearance. The total length, i.e. from head to heels, at the end of the eighth month is about 40 cm., and the weight varies between 2 and 2·5 kilograms.

FIG. 243.—Human embryo about eight and a half weeks old. (His.)

Ninth Month.—The lanugo has largely disappeared from the trunk. The umbilicus is almost in the middle of the body and the testes are in the scrotum. At full time the foetus weighs from 3 to 3·5 kilograms, and measures from head to heels about 50 cm.

OSTEOLOGY

THE general framework of the body is built up mainly of a series of bones supplemented in certain regions by pieces of cartilage; this bony and cartilaginous framework constitutes the *skeleton*.

In comparative anatomy the term skeleton has a wider application, since in some of the lower animals hard, protecting and supporting structures are developed in association with the integumentary system. In such animals the skeleton consists of an internal or deep skeleton, the *endoskeleton*; and an external or superficial, the *exoskeleton*. In the human subject the exoskeleton is very rudimentary, its only important representatives being the nails and the enamel of the teeth, and the term skeleton is, therefore, confined to the endoskeleton; this is divisible into an *axial* part, which includes the bones of the head and trunk, and an *appendicular* part, which comprises those of the extremities or limbs. The minute structure and the physical properties of bones are described on pages 17 to 24.

In the skeleton of the adult there are 206 bones, grouped as follows:—

Axial Skeleton	{	Vertebral column	26	
	{	Skull	22	
	{	Hyoid bone	1	
	{	Ribs and sternum	25	
			—	74
Appendicular Skeleton	{	Upper extremities	64	
	{	Lower extremities	62	
			—	126
		Auditory ossicles		6
			—	
		Total		206

Bones are divisible into four classes: *long*, *short*, *flat*, and *irregular*.

The **long bones** are found in the limbs, where they form levers; each consists of a body or shaft and two extremities. The *body* or *diaphysis* is cylindrical, with a central cavity termed the *medullary cavity*; the wall surrounding the cavity consists of dense, compact substance of considerable thickness in the middle part of the body, but becoming thinner towards the extremities; projecting into the medullary cavity is some spongy substance, scanty in the middle of the body, but plentiful towards the ends. The *extremities* are usually expanded, for purposes of articulation and muscular attachment; they consist of spongy substance surrounded by compact bone, and are usually developed from one or more separate centres of ossification termed *epiphyses*. The medullary cavity and the spaces in the spongy substance are filled with marrow (*medulla ossium*).

Short bones.—Where a part of the skeleton is intended for strength and compactness combined with limited movement, it is constructed of a number of short bones, as in the *carpus* and *tarsus*. These consist of spongy substance covered by a thin crust of compact bone.

Flat bones.—Where the principal requirement of the skeleton is to protect delicate structures, or provide broad surfaces for muscular attachment, the bones are expanded into plates, as in the skull and the scapula, and are composed of two thin layers of compact bone separated by a variable quantity of spongy

substance. In the cranial bones, the layers of compact bone are familiarly known as the *tables* of the skull; the outer table is thick and tough, the inner thin, dense, and brittle. The intervening spongy substance is called the *diploe*, and this, in certain regions of the skull, undergoes absorption, and spaces filled with air (*air-sinuses*) are left between the two tables of the skull.

The irregular bones, from their peculiar form, cannot be grouped under the preceding heads. They consist of spongy substance enclosed within a thin layer of compact bone.

Surfaces of bones.—On the surfaces of the bones are eminences and depressions, either articular or non-articular. *Articular eminences* are seen in the heads of the humerus and femur; and *articular depressions* in the glenoid cavity of the scapula, and the acetabulum of the hip-bone. *Non-articular eminences* are designated according to their form. Thus, a broad, rough, uneven elevation is called a *tuberosity*, *trochanter*, *protuberance*, or *process*; a small, rough prominence, a *tubercle*; a sharp, slender, pointed eminence, a *spine*; a narrow, rough elevation of some length, a *ridge*, *crest*, or *line*. *Non-articular depressions* are also of variable form, and are described as *fossæ*, *pits*, *depressions*, *grooves*, *furrows*, *fissures*, *notches*, &c

THE VERTEBRAL COLUMN (COLUMNA VERTEBRALIS)

The vertebral column is a flexuous and flexible column, formed of a series of bones called *vertebræ*. These are thirty-three in number, and are grouped under the names *cervical*, *thoracic*, *lumbar*, *sacral*, and *coccygeal* according to the regions they occupy; there are seven vertebræ in the cervical region, twelve in the thoracic, five in the lumbar, five in the sacral, and four in the coccygeal.

The cervical, thoracic, and lumbar vertebra remain separate from one another throughout life, and are therefore known as *true* or *movable* vertebræ; the sacral and coccygeal vertebræ, on the other hand, are termed *false* or *fixed* vertebræ, because they are united in the adult to form two bones, viz. the *sacrum* and *coccyx*, formed respectively by the fused sacral and coccygeal vertebræ.

GENERAL CHARACTERISTICS OF A VERTEBRA

With the exception of the first and second cervical, the true or movable vertebræ present certain common characteristics which are best studied by examining one from the middle of the thoracic region.

A typical vertebra (fig. 244) consists of two principal parts, an anterior, the *body*, and a posterior, the *vertebral arch*, these enclose a foramen, the *vertebral foramen*.

In the articulated vertebral column the bodies form a pillar for the support of the head and trunk, and the vertebral foramina constitute a canal in which the medulla spinalis or spinal cord is lodged and protected. Between every pair of vertebræ are two *intervertebral foramina* one on either side, for the transmission of the spinal nerves and vessels.

The body of a vertebra is more or less cylindrical in shape; its upper and lower surfaces are flattened and rough, and give attachment to the intervertebral fibrocartilages, and each presents a rim around its circumference. In front, it is convex from side to side and concave from above downwards; behind, it is slightly concave from side to side and flat from above downwards. On its anterior surface are a few small apertures for the passage of nutrient vessels; on its posterior surface is a large, irregular aperture (occasionally more than one) for the exit of the basivertebral veins from the body of the vertebra.

The *vertebral arch* consists of a pair of *pedicles* or *roots* and a pair of *laminae*; it supports seven *processes*, viz. four *articular*, two *transverse* and one *spinous*.

The *pedicles*, or *roots of the vertebral arches*, are short, thick processes, which project backwards, one on either side, from the body, at the

junction of its posterior and lateral surfaces. The concavities above and below the pedicles are named the *vertebral notches*; and when the vertebrae are articulated with one another, the notches of each contiguous pair of bones form the *intervertebral foramina*, already referred to.

The laminae are two broad plates directed backwards and medialwards from the pedicles. They fuse in the middle line posteriorly, and so complete

FIG. 244.—A typical thoracic vertebra, viewed from above.

the posterior boundary of the vertebral foramen. Their upper borders and the lower parts of their anterior surfaces are rough for the attachment of the *ligamenta flava*.

The spinous process is directed backwards and downwards from the junction of the laminae, and serves for the attachment of muscles and ligaments.

The articular processes, two superior and two inferior, spring from the junctions of the pedicles and laminae. The superior processes project upwards, and their articular surfaces are directed more or less backwards; the inferior project downwards, and their surfaces look more or less forwards.

The transverse processes project lateralwards from the points where the laminae join the pedicles; they serve for the attachment of muscles and ligaments.

FIG. 245.—Sagittal section of a lumbar vertebra.

Structure of a vertebra (fig. 245).—The body is composed of spongy substance covered by a thin coating of compact bone; the latter is perforated by numerous orifices for the passage of vessels; the interior of the body is traversed by one of two large canals, for the reception of veins, which converge towards the large

aperture on the posterior surface of the body. The vertebral arch and the processes projecting from it have thick coverings of compact substance.

CERVICAL VERTEBRÆ (VERTEBRÆ CERVICALES)

The cervical vertebrae (figs. 246, 247), seven in number, are the smallest of the true vertebrae, and can be readily distinguished from the thoracic or lumbar vertebrae by the presence of a foramen in each transverse process.

The first, second, and seventh cervical vertebrae present exceptional features; the following characteristics are common to the remaining four.

The *body* is small, and broader from side to side than from before backwards. The anterior and posterior surfaces are flattened and of equal depth, but the anterior is placed on a lower level than the posterior, and its inferior border is prolonged downwards, so as to overlap the upper and front part of the succeeding vertebra. The superior surface is concave transversely, and presents an

FIG. 246.—A typical cervical vertebra, from above.

upwardly projecting lip on either side; the inferior surface is saddle-shaped, i.e. concave from before backwards, convex from side to side, and presents laterally shallow concavities which receive the projecting lips of the subjacent vertebra. The *pedicles* are directed lateralwards and backwards, and are attached to the body midway between its upper and lower borders, so that the superior and inferior vertebral notches are of equal depth; the superior notch is, however, narrower than the inferior. The *laminae* are narrow, and thinner above than below; the *vertebral foramen* is large, and of triangular form. The *spinous process* is short and bifid, the two parts being often of unequal size. The *superior* and *inferior articular processes* on either side are fused to form an *articular pillar*, which projects lateralwards from the junction of the pedicle

FIG. 247.—Side view of a typical cervical vertebra.

and lamina. The articular facets are flat and of an oval form; the superior look backwards, upwards, and slightly medialwards; the inferior forwards, downwards, and slightly lateralwards. In the third and fourth vertebrae the lateral surfaces of the articular pillars are grooved for the accommodation of the medial branches of the posterior divisions of the corresponding cervical nerves. The *transverse processes* are each pierced by the *foramen transversarium*, which, in the upper six vertebrae, gives passage to

* Some markings on the cervical vertebrae. Wood Jones, *Journal of Anatomy and Physiology*, 1911.

the vertebral artery and vein and a plexus of sympathetic nerves. Each process consists of an anterior and a posterior part. The anterior portion is the homologue of the rib in the thoracic region, and is therefore named the *costal process*; it arises from the side of the body, is directed lateralwards in front of the foramen, and ends in a tubercle, the *tuberculum anterius*. The posterior part, the true transverse process, springs from the vertebral arch behind the foramen transversarium, and is directed forwards and lateralwards; it ends in a flattened vertical tubercle, the *tuberculum posterius*. Lateral to the foramen transversarium the anterior and posterior tubercles are united by a curved bar of bone, the concavity or sulcus on the upper surface of which accommodates the anterior division of the corresponding spinal nerve. This sulcus is deeper, wider, and more downwardly directed in the fifth and sixth than in the third and fourth vertebrae.*

Chassaignac pointed out that the common carotid artery can be compressed against the anterior tubercle of the transverse process of the sixth cervical vertebra; this tubercle therefore is named the *tuberculum caroticum* or *Chassaignac's tubercle*. It also constitutes an important guide to the vertebral artery.

The first cervical vertebra (fig. 248) is named the atlas because it supports the globe of the head. Its chief peculiarity is that it has no body, and

FIG. 248.—First cervical vertebra, or atlas, from above.

this is due to the fact that the body of the atlas has fused with that of the second vertebra. It has no spinous process but is ring-like, and consists of an anterior and a posterior arch and two lateral masses. The *anterior arch* forms about one-fifth of the ring: its front surface is convex, and at its centre is the *anterior tubercle* for the attachment of parts of the Longus colli muscles; posteriorly it is concave, and marked by a smooth, oval or circular facet (fovea dentis), for articulation with the dens or odontoid process of the epistropheus or axis. The upper and lower borders respectively give attachment to the anterior atlanto-occipital membrane and the anterior atlanto-epistropheal ligament; the former connects the atlas with the occipital bone, the latter with the epistropheus. The *posterior arch* forms about two-fifths of the ring: at the centre of its posterior surface is the *posterior tubercle*, which is the rudiment of a spinous process and gives origin to the Recti capitis posteriores minores. The small size of this process prevents it from interfering with the movements between the atlas and the skull. The upper edge of the central part of the posterior arch is rounded and affords attachment to the posterior atlanto-occipital membrane, while immediately behind the superior articular process of each lateral mass is a groove, the *sulcus arteriæ vertebralis*, sometimes converted into a foramen by a bony spiculum which arches backwards from the posterior end of the

* The *costal element* of a cervical vertebra not only includes the portion which springs from the side of the body, but the anterior and posterior tubercles and the bar of bone which connects the latter (fig. 107).

superior articular process. This sulcus transmits the vertebral artery, which, after ascending through the foramen in the transverse process, winds round the lateral mass in a direction backwards and medialwards; it also transmits the suboccipital or first spinal nerve. On the under surface of the posterior arch, behind the articular facets, are the two shallow inferior vertebral notches. The lower border of the posterior arch gives attachment to the posterior atlanto-epistropheal ligament.

The *lateral masses* support the weight of the head; each carries two articular facets, a superior and an inferior. The superior facets are of large size, oval, concave, and approach each other in front, but diverge behind; they are directed upwards, medialwards, and a little backwards, and form cups for the reception of the condyles of the occipital bone, and are admirably adapted to the nodding movements of the head; occasionally they are constricted near their centres. Just below the medial margin of each superior facet is a small tubercle, for the attachment of the transverse ligament of the atlas; this ligament divides the ring of the atlas into two unequal parts—the anterior or smaller part receiving the dens or odontoid process of the epistropheus, the posterior transmitting the medulla spinalis and its membranes. The inferior articular facets are nearly circular in form, flattened or slightly convex and directed downwards and medialwards, articulating with the epistropheus, and permitting the rotatory movements of the head. The *transverse processes* are long and project lateralwards and downwards from the lateral masses; their anterior and posterior tubercles are fused into one mass. The foramen transversarium is large and is directed upwards and backwards.

The second cervical vertebra or epistropheus (axis) (figs. 249, 250) forms the pivot upon which the atlas, carrying the head, rotates. The chief

FIG. 249.—Second cervical vertebra, or epistropheus, from above.

characteristic of this bone is the strong tooth-like process, the *dens*, which projects perpendicularly from the upper surface of the body. The *body* is deeper in front than behind. On its anterior surface is a median ridge, separating two depressions for the attachment of the Longus colli muscles. Its under surface is concave from before backwards and convex from side to side. The *dens* (odontoid process) is about 1.5 cm. long, and exhibits a slight constriction, or neck, where it joins the body. On its anterior surface is an oval or nearly circular facet for articulation with that on the posterior surface of the anterior arch of the atlas. On the back of the neck, and frequently extending on to its lateral surfaces, is a shallow groove for the transverse ligament of the atlas, which retains the dens in position. The apex is pointed, and gives attachment to the *ligamentum apicis dentis*; below the apex, the process is somewhat enlarged and presents on either side a rough impression for the attachment of the lateral alar ligaments which connect the dens to the occipital bone. The internal structure of the dens is more compact than that of the body. The *pedicles* are broad and strong, especially in front, where they fuse with the sides of the body and the root of the dens. They are covered above by the superior articular surfaces. The *laminae* are thick and strong, and the vertebral foramen large but smaller than that of the atlas. The *transverse processes* are very small; each ends in a single tubercle and is perforated

by the foramen transversarium which is directed upwards and lateralwards. The *superior articular surfaces* are circular, slightly convex, directed upwards and slightly lateralwards, and are supported on the body, pedicles, and transverse processes; the *inferior* have the same direction as those of the typical cervical vertebrae. The *superior vertebral notches* are very shallow, and lie behind the articular processes; the *inferior* lie in front of the articular processes,

FIG. 250.—Second cervical vertebra, or epistropheus, from the side.

as in the typical cervical vertebrae. The *spinous process* is large and very strong; it is deeply channelled on its under surface, and has a bifid, tuberculated extremity.

The *seventh cervical vertebra* (fig. 251).—This vertebra is named the *vertebra prominens* because of its long and prominent spinous process. This process is thick, and nearly horizontal in direction; it is not bifurcated, but ends in a tubercle to which the lower end of the ligamentum nuchæ is attached.

FIG. 251.—Seventh cervical vertebra, from above.

The *transverse processes* are of considerable size; their posterior roots are large and prominent, the anterior small and faintly marked; the upper surface of each process has usually a shallow sulcus for the seventh cervical nerve, and the extremity of the process seldom presents more than a trace of division. The superior articular facets look almost directly backwards. The foramen transversarium is generally smaller than that in the other cervical vertebrae; rarely it is double, sometimes it is absent. On the left side it occasionally gives passage to the vertebral artery; sometimes the vertebral vein traverses it on both sides; but as a rule the artery

and vein pass in front of the transverse process. Occasionally the anterior roots of the transverse processes of this vertebra exist as separate bones, which extend lateralwards and forwards, and are known as *cervical ribs*.

THORACIC VERTEBRÆ (VERTEBRÆ THORACALES)

The thoracic vertebræ (fig. 252), twelve in number, increase in size from above downwards. All are distinguished by the presence of foveæ or facets on the sides of the bodies for articulation with the heads of the ribs; and all, except the eleventh and twelfth, by facets on the transverse processes, for articulation with the tubercles of the ribs.

The first, ninth, tenth, eleventh, and twelfth thoracic vertebræ present certain peculiarities, and must be specially considered (fig. 253).

In the middle part of the thoracic region the bodies are heart-shaped, and their anteroposterior and transverse diameters are about equal, but at the upper and lower ends of the region they resemble respectively those of the cervical and lumbar vertebræ. They are slightly thicker behind than in front, flat above and below, convex from side to side in front, deeply concave behind,

FIG. 252.—A typical thoracic vertebra, from the side.

and slightly constricted laterally and in front. They present on either side, two costal foveæ or facets, a superior near the root of the pedicle, and an inferior in front of the inferior vertebral notch; in the articulated vertebral column these foveæ form, with the intervertebral fibrocartilages, oval surfaces for the reception of the heads of the ribs. The *pedicles* are directed backwards and slightly upwards, and the inferior vertebral notches are of large size, and deeper than in the cervical or lumbar vertebræ. The *laminae* are broad, thick, and overlap those of subjacent vertebræ like tiles on a roof. The *vertebral foramen* is smaller than that of the cervical or lumbar vertebræ, and is of a circular form. The *spinous process* is long, triangular on coronal section, directed obliquely downwards, and ends in a tuberculated extremity. These processes overlap from the fifth to the eighth, but are less oblique in direction above and below these levels.* The *superior articular processes* are thin plates of bone projecting upwards from the junctions of the pedicles and laminae; their articular facets are almost flat, and are directed backwards and a little lateralwards and upwards. The *inferior articular processes* are fused to a considerable extent with the laminae, and project but slightly beyond their lower borders; their facets are

* In quadrupeds the majority of the spinous processes of the thoracic vertebræ project upwards and backwards, while those of the lumbar region are directed upwards and forwards. The change in inclination is effected in one of the lower thoracic vertebræ, the spine of which points almost directly upwards. This vertebra is known as the *anticlinal*, and in man its representative is the eleventh thoracic.

directed forwards and a little medialwards and downwards. The *transverse processes* arise from the arch behind the superior articular processes and pedicles; they are thick, strong, and of considerable length, directed obliquely backwards and lateralwards, and each ends in a clubbed extremity, on the front of which is a small costal fovea or facet, for articulation with the tubercle of a rib. In

FIG. 253.—Peculiar thoracic vertebræ.

the upper six thoracic vertebræ the costal foveæ are concave, and are placed on the anterior surfaces of the transverse processes; in the vertebræ from the seventh to the tenth inclusive the costal foveæ are flat and placed on the upper margin of the transverse processes.

The first thoracic vertebra has on either side of the upper part of the body a complete fovea for the head of the first rib, and at the lower part of the body a small fovea for the upper half of the head of the second rib. The body resembles that of the seventh cervical vertebra, being broad transversely,

while its upper surface is concave in the same direction, and lipped on either side. The *superior articular surfaces* are directed upwards and backwards; the *spinous process* is thick, long, and almost horizontal. The *transverse processes* are long, and the superior vertebral notches are deeper than those of the other thoracic vertebræ.

The ninth thoracic vertebra may have no inferior costal foveæ, but in some cases these are present.

The tenth thoracic vertebra has usually a complete costal fovea, placed partly on the lateral surface of the pedicle, for the head of the tenth rib, but the fovea for the head of this rib is sometimes completed by the body of the ninth vertebra.

In the eleventh thoracic vertebra the *body* approaches in form and size those of the lumbar vertebræ. The *foveæ* for the heads of the ribs are large, and placed chiefly on the pedicles, which are thicker and stronger in this and the next vertebra than in any other part of the thoracic region. The *spinous process* is short, and nearly horizontal in direction. The *transverse processes* are very short, tuberculated at their extremities, and have no costal foveæ.

The twelfth thoracic vertebra has the same general characteristics as the eleventh, but may be distinguished from it by its inferior articular surfaces being convex and directed lateralwards, like those of the lumbar vertebræ; by the body, laminae, and spinous process, which resemble those of lumbar vertebræ; and by each transverse process being a short irregular knob subdivided into superior, inferior, and lateral tubercles: the superior and inferior tubercles correspond to the mamillary and accessory processes of the lumbar vertebræ. Traces of similar tubercles are found on the transverse processes of the tenth and eleventh thoracic vertebræ.

LUMBAR VERTEBRÆ (VERTEBRÆ LUMBALES)

The lumbar vertebræ (figs. 254, 255), five in number, are the largest segments of the movable part of the vertebral column, and can be distinguished

FIG. 254.—A lumbar vertebra, from the side.

by the absence of foramina in their transverse processes, and of costal foveæ on the sides of the bodies.

The *body* is large, wider from side to side than from before backwards, and a little thicker in front than behind. It is flattened above and below, concave behind, and constricted in front, and at the sides. The *pedicles* are strong, and directed backwards from the upper part of the body; consequently, the inferior vertebral notches are of considerable depth. The *laminae* are broad, short, and strong; the *vertebral foramen* is triangular, larger than in the thoracic, but

smaller than in the cervical region. The *spinous process* is thick, broad, and somewhat quadrilateral; it projects backwards and ends in a rough, uneven border. The *superior* and *inferior articular processes* project respectively upwards and downwards from the junctions of pedicles and laminae. The facets on the superior processes are concave, and look backwards and medialwards; those on the inferior are convex, and are directed forwards and lateralwards. The superior articular processes are wider apart than the inferior, since in the articulated column the inferior articular processes are embraced by the superior processes of the subjacent vertebra. The *transverse processes* are situated in front of the articular processes instead of behind them as in the thoracic vertebrae, and are homologous with the ribs. Those of the upper three vertebrae arise from the junctions of the pedicles and laminae, and are long, slender, and horizontally directed; those of the lower two vertebrae incline a little upwards and spring from the pedicles and posterior parts of the bodies.

FIG. 255.—A lumbar vertebra, from above and behind.

The transverse process of the first lumbar vertebra is sometimes developed as a separate piece which may remain permanently ununited with the rest of the bone, thus forming a lumbar rib. Of the tubercles noticed in connexion with the transverse processes of the lower thoracic vertebrae, the *superior* is connected in the lumbar region with the posterior part of the superior articular process, and is named the *mamillary process*; the *inferior* is situated at the posterior part of the base of the transverse process, and is called the *accessory process* (fig. 255).*

The fifth lumbar vertebra (fig. 256) is characterised by its body being considerably deeper in front than behind, a condition which accords with the prominence of the sacrovertebral articulation; by the small size of its spinous process; by the wide interval between the inferior articular processes; and by the thickness of its transverse processes, which spring from the body as well as from the pedicles.

* The mamillary and accessory processes are merely muscular processes which, represented and conjoined in the thoracic region, become separated in the lumbar region by the passage of the internal branch of the posterior division of the lower thoracic and lumbar nerves between them. (Wood-Jones, *Journal of Anatomy and Physiology*, vol. xlvii., p. 118.)

THE SACRUM (Os SACRUM)

The sacrum is a large, triangular bone formed by the fusion of the five sacral vertebrae. It is situated in the lower part of the vertebral column and at the upper and posterior part of the pelvic cavity, where it is inserted like a wedge between the two hip-bones; its upper part or base articulates with the fifth lumbar vertebra, its apex with the coccyx. It is rather narrower at the level of the second vertebra than at the level of the third. It is curved longitudinally, and placed very obliquely, its base projecting forwards and forming the prominent *sacrovertebral angle* when articulated with the last lumbar vertebra; the central part of the bone is projected backwards, so as to give increased capacity to the pelvic cavity. The sacrum has a pelvic, a dorsal, and two lateral surfaces, a base, an apex, and a central canal.

Fig. 256.—Fifth lumbar vertebra, from above.

The *pelvic surface* (fig. 257) is concave from above downwards, and slightly so from side to side. Its middle part is crossed by four transverse ridges, which correspond in position with the original planes of separation between the five segments of the bone; the portions between the ridges are the bodies of the sacral vertebrae. The body of the first segment is of large size, and in form resembles that of a lumbar vertebra; the succeeding ones diminish from above downwards, are flattened from before backwards, and curved to accommodate themselves to the form of the sacrum, being concave in front, and convex behind. Lateral to the ridges are the four *anterior sacral foramina*, somewhat rounded in form, diminishing in size from above downwards, and directed lateralwards and forwards: they open into the sacral canal and give exit to the anterior divisions of the sacral nerves, and entrance to the lateral *sacral arteries*. Lateral to these foramina are the *lateral parts* of the sacrum, each consisting of five separate segments at an early period of life; in the adult, these are blended with the bodies and with each other. Each lateral part is traversed by four broad, shallow grooves, which lodge the anterior divisions of the sacral nerves, and are separated from one another by prominent ridges of bone which give origin to the *Piriformis*.

If a sagittal section be made through the centre of the sacrum (fig. 261), the bodies are seen to be united at their circumferences by bone, wide intervals

being left centrally, which, in the recent state, are filled by the intervertebral fibrocartilages. In some specimens the union is more complete between the lower than between the upper segments.

The *dorsal surface* (fig. 258) is convex and narrower than the pelvic. In the middle line is the *medial sacral crest*, surmounted by the rudimentary spinous processes of the upper three or four sacral vertebrae. On either side of this crest is the *sacral groove*, which gives origin to the Multifidus, the floor of the groove being formed by the united laminae of the vertebrae. The laminae of the fifth sacral vertebra, and sometimes those of the fourth, fail to meet behind, and thus a deficiency (*hiatus sacralis*) occurs in the posterior wall of the sacral canal. Lateral to each sacral groove is a linear series of tubercles produced by the fusion of the articular processes which together form the

FIG. 257.—Sacrum, pelvic surface.

indistinct *sacral articular crests*. The articular processes of the first sacral vertebra are large; their facets are oval or circular in shape, and are concave from side to side; they look backwards and medialwards, and articulate with the facets on the inferior processes of the fifth lumbar vertebra. The tubercles which represent the inferior articular processes of the fifth sacral vertebra are prolonged downwards as rounded processes, which are named the *sacral cornua*, and are connected to the cornua of the coccyx. Lateral to the sacral articular crests are the four *posterior sacral foramina*; they are smaller in size and less regular in form than the anterior foramina, and transmit the posterior divisions of the sacral nerves. Lateral to the posterior sacral foramina are the *lateral sacral crests*, formed by the fused transverse processes of the sacral vertebrae. The transverse tubercles of the first sacral vertebra are large and very distinct; they and the transverse tubercles of the second vertebra, give attachment to the short posterior sacro-iliac ligaments; those of the third vertebra give attachment to the long posterior sacro-iliac ligaments; and those of the fourth and fifth to the sacrotuberous ligaments.

The *lateral surface* (fig. 259) is broad above, but narrowed into a thin edge below. On the upper part is an ear-shaped surface, the *auricular surface*, for articulation with the ilium; behind this is a rough area, the *sacral tuberosity*, on which are three deep impressions, for the attachment of the posterior sacroiliac ligament. The thin, lower part of the lateral surface gives attachment to the sacrotuberous and sacrospinous ligaments, to some fibres of the *Glutæus maximus* behind, and to the *Coccygeus* in front. It ends below in a projection called the *inferior lateral angle*; the notch on the medial side of this angle is converted into a foramen by the transverse process of the first piece of the coccyx, and transmits the anterior division of the fifth sacral nerve.

FIG. 258.—Sacrum, dorsal surface.

The *base* of the sacrum (fig. 260) is transversely expanded, and is directed upwards and forwards; it somewhat resembles the upper surface of the last lumbar vertebra. In the middle is the large oval upper surface of the body of the first sacral vertebra, which is connected with the under surface of the body of the last lumbar vertebra by an intervertebral fibrocartilage; the anterior projecting edge of the body is named the *promontory*. Behind the body is the superior orifice of the sacral canal, triangular in shape and completed posteriorly by the arch of the first sacral vertebra. On either side of the body is a large triangular plate called the *ala sacralis*; its upper surface is slightly concave from side to side, convex from before backwards, and in the articulated pelvis is continuous with the iliac fossa. The posterior third of the ala represents the transverse process, and the anterior two-thirds, the costal process of the first sacral vertebra. The superior articular processes are attached to the body of the first sacral vertebra and to the alæ by short thick pedicles; they are oval, concave, directed backwards and medialwards, like the superior articular processes of the lumbar vertebrae. On the upper surface of each pedicle is a vertebral notch, which forms the lower part of the foramen between the last lumbar and first sacral vertebrae.

FIG. 259.—Lateral surfaces of sacrum and cœcyx.

FIG. 260.—Base of sacrum.

arches. At birth the vertebra consists of three pieces, viz. the body and the halves of the vertebral arch. During the first year the halves of the arch unite behind, the union taking place first in the lumbar region and then extending upwards through the thoracic and cervical regions. In the upper cervical vertebrae the bodies unite with the arches about the third year; in the lower lumbar vertebrae union is not completed until the sixth year. Until puberty, the upper and under surfaces of the bodies and the ends of the transverse and spinous processes are cartilaginous, but about the sixteenth year (fig. 265) five secondary centres appear, one for the tip of each transverse process, one for the end of the spinous process, one each for the circumferential parts of the upper and lower surfaces of the body (fig. 266). These fuse with the rest of the bone about the age of twenty-five. In the bifid spines of the cervical vertebrae there are two secondary centres.

Exceptions to this mode of development occur in the first, second, and seventh cervical vertebrae, and in the lumbar vertebrae.

The atlas or first cervical vertebra, is usually ossified from three centres (fig. 267). One appears in each lateral mass about the seventh week of foetal life, and gradually extends into the posterior arch, where they unite between the third and fourth years, either directly or through the medium of a separate centre. At birth, the anterior arch consists of cartilage; in this a separate centre appears about the end of the first year, and unites with the lateral masses between the sixth and eighth years—the lines of union extending across the anterior portions of the superior articular facets. Occasionally the anterior arch is formed by the forward extension and ultimate union of the two lateral masses; sometimes it is ossified from two laterally placed centres.

The epistropheus, or second cervical vertebra, is ossified from five primary and two secondary centres (fig. 268). The vertebral arch is ossified from two centres,

Lateral epiphysis

the fourth or fifth month. About the sixth month of foetal life, two laterally placed centres appear in the base of the dens or odontoid process, and join before birth to form a conical mass, deeply cleft above. A wedge-shaped piece of cartilage fills the cleft and forms the summit of the process; in this a centre appears about the second year and unites with the main mass about the twelfth year. The base of the dens is separated from the body of the epistropheus by a cartilaginous disc, the circumference of which ossifies, but the centre remains cartilaginous until advanced age. In this cartilage, rudiments of the lower epiphysial lamella of the atlas and the upper epiphysial lamella of the epistropheus may sometimes be found. In addition to these there is a centre for a thin epiphysial plate on the under surface of the body of the bone.

The seventh cervical vertebra.—The costal processes of this vertebra are usually ossified from separate centres which appear about the sixth month of foetal life, and join the body and transverse processes between the fifth and sixth years. As already stated (p. 166), the costal processes may persist as separate pieces, and grow lateralwards and forwards, to constitute cervical ribs.

Separate ossific centres have also been found in the costal processes of the fourth, fifth, and sixth cervical vertebrae.

The lumbar vertebrae (fig. 269) have each two additional centres, for the mamillary processes.

Sacrum (figs. 270 to 273).—Each sacral vertebra is ossified from three primary centres, one for the body and two for the vertebral arch. Two epiphysial plates are ossified for each body, one for the upper and the other for the lower surface.

The anterior portions of the lateral parts of the sacrum have six additional (costal) centres, two for each of the first three vertebrae; these appear above and lateral to the anterior sacral foramina (figs. 270*, 271).

Two epiphysial plates are developed on each lateral surface of the sacrum (fig. 272*, 273); one for the auricular surface, and another for the thin edge of bone below this surface.†

† The ends of the spinous processes of the upper three sacral vertebrae are sometimes developed from separate epiphyses, and Fawcett (*Anatomischer Anzeiger*, 1907, Bd. xxx.) has pointed out that a number of epiphyses may be seen in the sacrum at the age of eighteen years. These are distributed as follows: One for each of the two mamillary processes of the first sacral vertebra; twelve—six on either side—in connexion with the costal elements (two each for the first and second and one each for the third and fourth vertebrae); and eight for the transverse processes—four on either side—one each for the first, third, fourth, and fifth. He is further of opinion that the lower part of each lateral surface of the sacrum is formed by the extension and union of the costal epiphyses of the third and fourth segments and the 'transverse' epiphyses of the fourth and fifth segments.

Periods of ossification.—Ossification commences in the bodies of the sacral vertebrae as follows: in the first about the eighth or ninth week of foetal life; in the second about the tenth week; and in the fourth and fifth between the fifth and eighth months. About the twelfth week of foetal life the vertebral arch of the first segment begins to ossify; and after the sixth month the costal centres for the lateral parts of the bone make their appearance. In the lower vertebrae the arches fuse with the bodies in the second year; in the first vertebra fusion does not occur until the fifth or sixth year. About the sixteenth year the epiphysal plates for the upper and under surfaces of the bodies are formed; and between the eighteenth and twentieth years those for the lateral surfaces of the bone make their appearance. During early life, the bodies of the sacral vertebrae are separated from each other by intervertebral fibrocartilages, but about the eighteenth year the bodies of the two lower vertebrae become united by bone, and the process of bony union gradually extends upwards, with the result that between the twenty-fifth and thirtieth years of life all the vertebrae are united (fig. 261).

Coccyx.—Each segment of the coccyx is ossified from one centre. The centres appear in the following order: in the first segment between the first and fourth years; in the second between the fifth and tenth years; in the third between the tenth and fifteenth years; in the fourth between the fourteenth and twentieth years. A secondary centre for each sacral cornu, and a pair of epiphysal plates for each of the rudimentary bodies have been described. As age advances, the segments unite with one another, the union between the first and second being frequently delayed until after the age of twenty-five or thirty years. At a late period of life, especially in females, the coccyx often fuses with the sacrum.

VERTEBRAL COLUMN AS A WHOLE

The vertebral column is situated in the median line, at the posterior part of the trunk. Its average length in the male is about 71 cm.; of this the cervical part measures 12·5 cm., the thoracic 28 cm., the lumbar 18 cm., and the sacrum and coccyx 12·5 cm. The average length of the female column is about 61 cm.

Curves.—Viewed laterally (fig. 274), the vertebral column presents cervical, thoracic, lumbar, and pelvic curves. The thoracic and pelvic curves are termed primary curves, because they alone are present during foetal life. The cervical and lumbar curves are compensatory or secondary, and are developed after birth, the cervical curve when the child is able to hold up its head (at three or four months), and to sit upright (about nine months), the lumbar at twelve or eighteen months when the child begins to walk. The cervical curve is convex forwards, and is the least marked of the four; it begins at the atlas, and ends at the middle of the second thoracic vertebra. The thoracic curve, concave forwards, extends from the middle of the second to the middle of the twelfth thoracic vertebra. The lumbar curve is convex anteriorly and is more pronounced in the female than in the male. It reaches from the middle of the last thoracic vertebra to the sacrovertebral angle, and the convexity of the lower three segments is greater than that of the upper two. The pelvic curve extends from the sacrovertebral articulation to the apex of the coccyx; its concavity is directed downwards and forwards.

In the upper part of the thoracic region of the vertebral column there is a slight lateral curvature, with its convexity directed towards the right side in right-handed persons. Some regard this curve as being due to the greater use and muscularity of the right arm, and in support of this explanation it has been found that in left-handed individuals the convexity of the curve is directed towards the left side. Others regard it as being produced by the aortic arch and upper part of the descending thoracic aorta—a view which is supported by the fact that in cases where the viscera are transposed and the aorta is consequently on the right side, the convexity of the curve is directed to the left.

Anterior surface.—When viewed from in front, the width of the bodies of the vertebrae is seen to increase from the second cervical to the first thoracic; there is then a slight diminution in the next three vertebrae; below this

FIG. 274.—Lateral view of the vertebral column.

there is again a gradual and progressive increase in width as low as the sacrovertebral angle. From this point there is a rapid diminution, to the apex of the coccyx.

The *posterior surface* of the vertebral column presents in the median line the spinous processes. In the cervical region (with the exception of the second and seventh vertebræ) these are short and horizontal, with bifid extremities. In the upper part of the thoracic region they are directed obliquely downwards; in the middle part they are almost vertical; in the lower part of the thoracic region, and in the lumbar region they are nearly horizontal. They are separated by considerable intervals in the cervical and lumbar regions, but are closely approximated in the middle of the thoracic region. Occasionally one of these processes deviates from the median line—a fact to be remembered in practice, as irregularities of this sort are attendant also on fractures or displacements of the vertebral column. On either side of the spinous processes is the *vertebral groove* formed by the laminae in the cervical and lumbar regions, where it is shallow, and by the laminae and transverse processes in the thoracic region, where it is deep and broad; these grooves lodge the deep muscles of the back. Lateral to the vertebral grooves are the articular processes, and still more laterally the transverse processes. In the thoracic region, the transverse processes stand backwards, on a plane considerably behind that of the same processes in the cervical and lumbar regions. In the cervical region, the transverse processes are placed in front of the articular processes, laterally to the pedicles and between the intervertebral foramina. In the thoracic region they are posterior to the pedicles, intervertebral foramina, and articular processes. In the lumbar region they are in front of the articular processes, and behind the intervertebral foramina.

The *lateral surfaces* are separated from the posterior surface by the articular processes in the cervical and lumbar regions, and by the transverse processes in the thoracic region. In front are the sides of the bodies of the vertebræ, marked in the thoracic region by the foveæ

for articulation with the heads of the ribs. Between the pedicles are the intervertebral foramina, oval in shape, smallest in the cervical and upper part of the thoracic regions, and gradually increasing in size to the last lumbar. These foramina transmit the spinal nerves and vessels, and are situated between the transverse processes in the cervical region, and in front of the transverse processes in the thoracic and lumbar regions.

The *base* of that portion of the vertebral column which is made up of the twenty-four movable vertebræ is formed by the under surface of the body of the fifth lumbar vertebra; and the *summit*, by the upper surface of the atlas.

The *vertebral canal* follows the different curves of the column; it is large and triangular in the cervical and lumbar regions, where movement is free, and is small and rounded in the thoracic region, where motion is more limited.

Applied Anatomy.—Occasionally the coalescence of the laminae is not completed, and consequently a cleft is left in the arches of the vertebræ, through which a protrusion of the spinal membranes (dura mater and arachnoid), and generally of the medulla spinalis and pia mater, takes place, constituting the malformation known as *spina bifida*. This condition is most common in the lumbosacral region, but it may occur in the thoracic or cervical region, or the arches throughout the whole length of the canal may remain incomplete.

The movable part of the vertebral column being constructed of a number of pieces, securely connected together and enjoying only a slight degree of movement between any two individual pieces, but permitting of a very considerable range as a whole, allows a sufficient degree of mobility without any material diminution of strength. The many joints of which the column is composed, together with the very varied movements to which it is subjected, render it liable to sprains; but, so closely are the individual vertebræ articulated that these sprains are rarely severe, and an amount of violence sufficiently great to produce tearing of the ligaments would tend rather to cause a dislocation or fracture. The further safety of the column and its slight liability to injury are provided for by its disposition in curves instead of in a straight line. For it is an elastic column, and must bend before it breaks; under these circumstances, being made up of three curves, it represents three columns, and greater force is required to produce bending of a short column than of a longer one of equal breadth and similar material. Again, the safety of the column is largely provided for by the presence between the bodies of the intervertebral fibrocartilages, which act as buffers in counteracting the effects of violent jars or shocks.

Fracture-dislocation of the vertebral column may be caused by direct or indirect violence. Fractures from indirect violence are the more common, and here the bodies of the vertebræ are compressed, while the arches are torn asunder; in fracture from direct violence, on the other hand, the arches are compressed and the bodies of the vertebræ separated from each other. It will therefore be seen that in both classes of injury the medulla spinalis is the part least likely to be injured, and may escape damage even where there has been considerable lesion of the bony framework. When a fracture-dislocation is produced by indirect violence, the displacement is almost always the same—the upper segment being driven forwards on the lower, so that the medulla spinalis is compressed between the body of the vertebra below and the arch of the vertebra above.

Lateral curvature of the vertebral column is a common affection in girls who are outgrowing their strength and who sit or stand long at lessons, and is due to the uneven transmission of weight down the column. In addition to the lateral displacement of the spinous processes there is a marked rotation of the bodies of the vertebræ, the displacement of which is far in excess of that of the spinous processes. When the curve is severe and the bones have actually become distorted, the condition is past cure.

Kyphosis is an affection in which there is an increase in the normal thoracic curve, and is due to bending forwards of the upper part of the body carrying the weight of the head. It is seen in rickety children, in rapidly growing adolescents, in senile conditions, and in certain diseases, such as osteo-arthritis and osteitis deformans. In the senile kyphosis often met with in aged labourers, the head is firmly fixed and bent forwards and downwards on to the chest, and the vertebral column is curved and rigid. The ribs are immobilised, the chest is flattened antero-posteriorly, and breathing becomes almost entirely abdominal. *Post mortem*, bony ankylosis of the ligaments and capsules of the intervertebral joints is found, with ossification of the ligamenta flava, interspinal and other ligaments.

It may be noted that in marked cases of spinal deformity the trachea and aorta follow closely along the line of a spinal curvature occurring in their vicinity, whereas the oesophagus between the tracheal bifurcation and the stomach often passes like a bowstring across the concavity of the curve.

Lordosis, on the other hand, is an exaggeration of the normal lumbar curve, the trunk being thrown backwards. This is always a compensatory curve, and occurs when, from

any cause such as pregnancy or tumours, the abdomen is enlarged. It is more strongly marked in cases of disease of the hip-joint where the joint is permanently retained in a flexed position; so that in order to bring the foot down to the ground the pelvis has to be tilted forwards, and this is accomplished by an increase of the normal lumbar curve.

Laminectomy.—The operation of laminectomy is performed in cases of pressure on the medulla spinalis, where the continuity of the nerve-tracts has not been completely destroyed. It consists of cutting down on and removing the laminae and spinous processes in the affected region, so as to relieve the medulla spinalis from pressure; but it is useless in cases of complete destruction of this structure. Laminectomy is chiefly performed (i) for fracture-dislocation; (ii) for localised pressure in cases of spinal caries, the object here being to remove the laminae against which the medulla spinalis is pressed by the inflammatory mass, and (iii) for the removal of tumours growing inside the vertebral canal and compressing the medulla spinalis. If such cases be taken early, very satisfactory results are obtained.

THE STERNUM.

The sternum (figs. 275 to 277) is an elongated, flattened bone, forming the middle portion of the anterior wall of the thorax. Its average length in the adult is about 17 cm., and is rather greater in the male than in the female. Its upper end supports the clavicles, and its margins articulate with the cartilages of the first seven pairs of ribs. It consists of three parts, named from above downwards, the *manubrium*, the *body*, and the *xiphoid process*; in early life the body consists of four segments or *sternebrae*. In its natural position the inclination of the bone is oblique from above, downwards and forwards. It is slightly convex in front, and concave behind; it is broad above, narrow at the junction of the manubrium with the body, below which it gradually widens as far as a point a little beneath the middle of the body, and then narrows to its lower extremity.

The *manubrium* is of a somewhat triangular form, broad and thick above, narrow below at its junction with the body. Its *anterior surface*, convex from side to side, concave from above downwards, is smooth, and affords attachment on either side to the sternal origins of the Pectoralis major and Sternocleidomastoideus. Its *posterior surface*, concave and smooth, gives origin on either side to the Sternohyoideus and Sternothyroideus. The *superior border* is thick, and presents at its centre the *jugal notch*; on either side of this notch is an oval articular surface, directed upwards, backwards, and lateralwards, for articulation with the sternal end of the clavicle. The *inferior border*, oval and rough, is covered in the recent state with a thin layer of cartilage, for articulation with the upper end of the body. The *lateral borders* are each marked above by a depression for the first costal cartilage, and below by a small articular facet, which, with a similar facet on the upper angle of the body, forms a notch for the reception of the sternal end of the costal cartilage of the second rib. Between the depression for the first costal cartilage and the facet for the second is a narrow, curved edge, which slopes from above downwards and medialwards.

The *body*, longer, narrower, and thinner than the manubrium, attains its greatest breadth close to the lower end. Its *anterior surface* is nearly flat, directed forwards and upwards, and marked by three ridges which cross the bone transversely opposite the third, fourth, and fifth articular depressions.* It affords attachment on either side to the sternal origin of the Pectoralis major. A *sternal foramen*, of varying size and form, is occasionally seen at the junction of the third and fourth pieces of the body. The *posterior surface*, slightly concave, is also marked by three transverse lines, less distinct, however, than those in front; from its lower part, on either side, the *Transversus thoracis* takes origin. The *upper end* is oval and articulates with the manubrium, the junction of the two forming the *sternal angle* (*angulus Ludovici* †). The *lower*

* Paterson (*The Human Sternum*, 1904) found that these ridges were absent in 26.7 per cent.; that a ridge existed opposite the third costal cartilage in 69 per cent.; opposite the fourth in 39 per cent.; and opposite the fifth in 4 per cent.

† Named after the French surgeon Antoine Louis, 1723-1792. The Latin term *angulus Ludovici* is not infrequently mistranslated into English as 'the angle of Ludwig.'

end is narrow, and articulates with the xiphoid process. Each *lateral border* (fig. 277), at its superior angle, has a small facet, which with a similar facet on the manubrium, forms a cavity for the reception of the sternal end of the cartilage of the second rib; below this are four angular depressions which receive the sternal ends of the cartilages of the third, fourth, fifth, and sixth

FIG. 275.—Anterior surface of sternum and costal cartilages.

ribs; the inferior angle has a small facet, which, with a corresponding one on the xiphoid process, forms a notch for the cartilage of the seventh rib. These articular depressions are separated by a series of curved interarticular intervals, which diminish in length from above downwards, and correspond to the intercostal spaces.

It will be observed that most of the cartilages of the true ribs articulate with the sternum at the lines of junction of its primitive component segments; this is well seen in

many of the lower animals, where the parts of the bone remain ununited longer than in man.

The **xiphoid process** is the smallest piece ; it is thin and elongated, cartilaginous in youth, but more or less ossified at its upper part in the adult. Its **anterior surface** affords attachment on either side to the anterior costoxiphoid ligament and a small part of the Rectus abdominis ; its **posterior surface**, to the posterior costoxiphoid ligament and to some of the fibres of the Diaphragm and Transversus thoracis ; its **lateral borders**, to the aponeuroses of the abdominal muscles. Above, it articulates with the lower end of the body of the bone, and on the front of each superior angle is a facet for part of the cartilage of

FIG. 276.—Posterior surface of sternum.

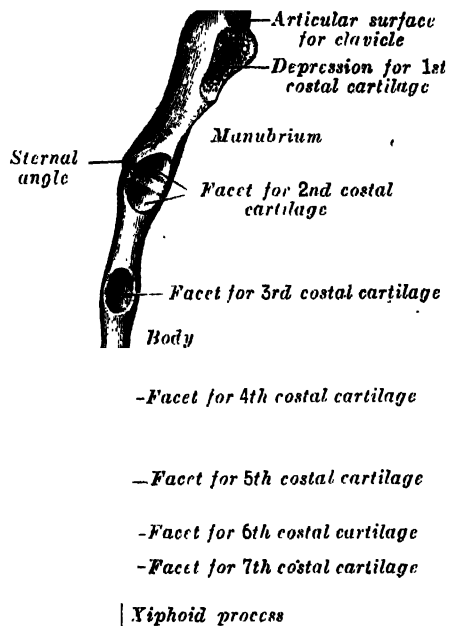

FIG. 277.—Lateral border of sternum.

the seventh rib ; its pointed inferior extremity gives attachment to the linea alba. The xiphoid process varies much in form ; it may be broad and thin, pointed, bifid, perforated, curved, or deflected considerably to one or other side.

Structure.—The sternum is composed of highly vascular spongy substance covered by a layer of compact bone which is thickest on the manubrium between the articular facets for the clavicles.

Ossification.—The sternum originally consists of two cartilaginous *sternal plates*, one on either side of the median plane. Opposite the first seven pairs of ribs these plates fuse with each other in the middle line to form the cartilaginous sternum. The bone is ossified from six centres : one for the manubrium, four for the body, and one for the xiphoid process (fig. 278). These centres appear in the intervals between the articular depressions for the costal cartilages, in the following order : in the manubrium and first piece of the body, during the sixth month of foetal life ; in the second and third pieces of the body, during the seventh month of foetal life ; in its fourth piece, shortly before birth ; and in the xiphoid process, in the third year or much later.* Two small episternal centres sometimes appear, one on either

* Paterson (*op. cit.*) found the fourth or lowest centre for the body present only in 26·9 per cent. of cases.

side of the jugular notch ; they are probably vestiges of the episternal bone of the monotremata and lizards. The manubrium may have two, three, or more centres ; when two are present, they are generally situated one above the other, the upper being the larger. The first segment of the body has seldom more than one centre ; but the second, third, and fourth segments are often ossified from two laterally placed centres, the incomplete union of which explains the occurrence of the foramen or fissure which is occasionally seen in this part of the bone. Union between the centres of the body begins about puberty, and proceeds from below upwards (fig. 279) ; by the age of twenty-five they are all united. The xiphoid process usually fuses with the body about the age of forty years, but may remain ununited in old age.

FIG. 278.—Ossification of the sternum.

FIG. 279.

In advanced life the manubrium is occasionally joined to the body by bone, but when this takes place the bony substance is generally only superficial, the central portion of the intervening cartilage remaining unossified.

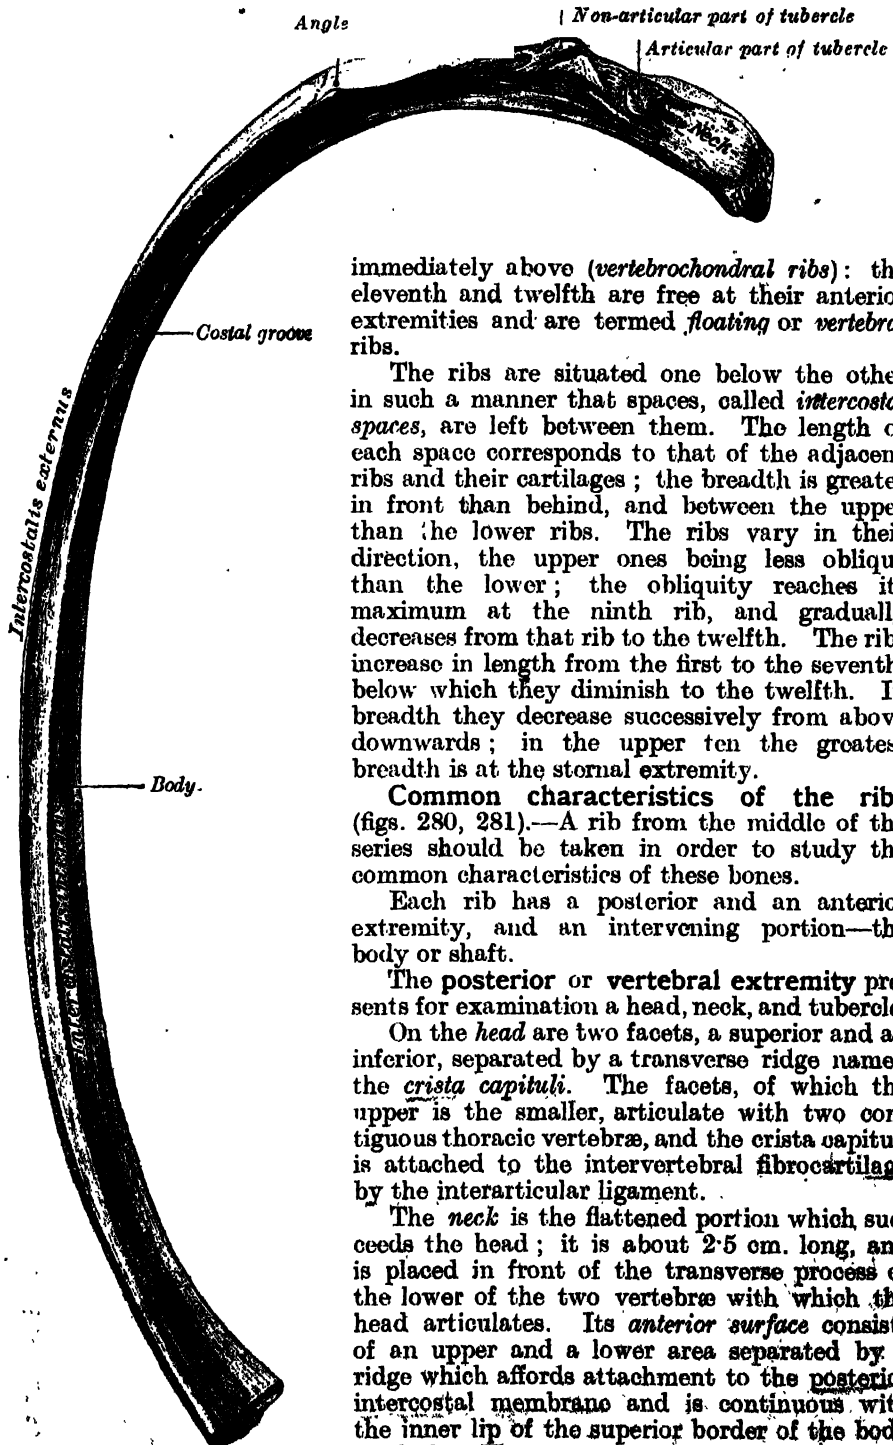

THE RIBS (COSTÆ)

The ribs are elastic arches of bone, which are connected behind with the vertebral column, and form a large part of the skeleton of the thorax. They are twelve in number on either side ; but this number may be increased by the development of a cervical or lumbar rib, or may be reduced to eleven. The first seven are connected in front, through the intervention of the costal cartilages, with the sternum (fig. 275) ; they are called *true ribs* (costæ veræ).*

* Sometimes the eighth rib cartilage articulates with the sternum ; this condition occurs more frequently on the right than on the left side.

The remaining five are *false ribs* (*costæ spuriae*); of these the cartilages of the eighth, ninth and tenth are each joined to the cartilage of the rib

FIG. 290.—A central rib of the left side. Inferior aspect.

immediately above (*vertebrochondral ribs*): the eleventh and twelfth are free at their anterior extremities and are termed *floating* or *vertebral ribs*.

The ribs are situated one below the other in such a manner that spaces, called *intercostal spaces*, are left between them. The length of each space corresponds to that of the adjacent ribs and their cartilages; the breadth is greater in front than behind, and between the upper than the lower ribs. The ribs vary in their direction, the upper ones being less oblique than the lower; the obliquity reaches its maximum at the ninth rib, and gradually decreases from that rib to the twelfth. The ribs increase in length from the first to the seventh, below which they diminish to the twelfth. In breadth they decrease successively from above downwards; in the upper ten the greatest breadth is at the sternal extremity.

Common characteristics of the ribs (figs. 280, 281).—A rib from the middle of the series should be taken in order to study the common characteristics of these bones.

Each rib has a posterior and an anterior extremity, and an intervening portion—the body or shaft.

The **posterior** or **vertebral extremity** presents for examination a head, neck, and tubercle.

On the *head* are two facets, a superior and an inferior, separated by a transverse ridge named the *crista capituli*. The facets, of which the upper is the smaller, articulate with two contiguous thoracic vertebrae, and the *crista capituli* is attached to the intervertebral fibrocartilage by the interarticular ligament.

The *neck* is the flattened portion which succeeds the head; it is about 2.5 cm. long, and is placed in front of the transverse process of the lower of the two vertebrae with which the head articulates. Its *anterior surface* consists of an upper and a lower area separated by a ridge which affords attachment to the posterior intercostal membrane and is continuous with the inner lip of the superior border of the body or shaft. The upper area, of varying size and

more or less triangular in shape, is separated from the posterior intercostal membrane by some fatty tissue; the lower is smooth and covered by the

costal pleura. Its *posterior surface* is rough for the attachment of the ligament of the neck of the rib, and perforated by numerous foramina. On its *superior border* is a rough crest, the *crista colli costæ*, for the attachment of the anterior costo-transverse ligament; from this crest a line can be followed into the outer lip of the superior border of the body or shaft. Its *inferior border*, more or less rounded, gives attachment to the posterior intercostal membrane and is continuous laterally with the superior border of the costal groove.

On the posterior surface of the rib at the junction of the neck and body, and nearer the lower than the upper border, is the *tubercle*; it is more prominent in the upper than in the lower ribs, and consists of an articular and a non-articular portion. The *articular portion*, the lower and more medial, has a small, oval surface for articulation with the end of the transverse process of the lower of the two vertebræ to which the head is connected. The *non-articular portion* is a rough elevation, and affords attachment to the ligament of the tubercle.

The *body or shaft* is thin and flat, with an external and an internal surface; and a superior and an inferior border. The *external surface* is convex, smooth,

FIG. 281.—A central rib of the left side viewed from behind.

and marked, a little in front of the tubercle, by a prominent line, directed downwards and lateralwards; this gives attachment to a tendon of the *ilio-costalis muscle*, and is called the *angle*. At this point the bone is bent in two directions, and at the same time twisted on its long axis. If the rib be laid upon its lower border, the portion of the body in front of the angle rests upon this border, while the portion behind the angle is bent medialwards and at the same time tilted upwards; as the result of the twisting, the external surface looks downwards behind the angle and slightly upwards in front. The distance between the angle and the tubercle is progressively greater from the second to the tenth ribs. Between the angle and the tubercle the external surface is rounded, rough, and irregular, and serves for the attachment of the *Longissimus dorsi*. Near the sternal end of the external surface is an indistinct oblique line, the *anterior angle*. The *internal surface* is concave, smooth, directed a little upwards behind the angle, a little downwards in front of it, and is marked by a ridge which commences at the lower extremity of the head; this ridge is strongly marked as far as the angle, and is lost at the junction of the anterior and middle thirds of the bone. Between it and the inferior border is the *costal groove*, for the intercostal vessels and nerve; within the groove are seen the orifices of numerous small foramina for nutrient vessels, which traverse the shaft obliquely from before backwards. At the posterior part of the bone, this groove occupies the inferior border, but just in front of the angle, where it is deepest and broadest, it is on the internal surface. The

superior edge of the groove is rounded and serves for the attachment of an *Intercostalis internus*; it is continuous behind with the inferior border of the neck. The inferior edge of the costal groove constitutes the *inferior border* of the rib, and gives attachment to an *Intercostalis externus*. The *superior border*, thick and rounded, is marked by an external and an internal lip, more distinct behind than in front; the former gives attachment to an *Intercostalis externus*, the latter to an *Intercostalis internus*.

On the *anterior or sternal extremity* is an oval, cup-shaped depression, into which the lateral end of the costal cartilage is received.

The first, second, tenth, eleventh, and twelfth ribs present certain variations, and require special consideration.

The first rib (fig. 282) is the most curved and usually the shortest of all the ribs; it is broad and flat, its surfaces looking upwards and downwards, and its borders inwards and outwards. The *head* is small, rounded, and has only a single, nearly circular, articular facet, which articulates with the upper

First and second ribs

part of the side of the body of the first thoracic vertebra. The *neck* is somewhat rounded. The *tubercle*, thick and prominent, is directed upwards and backwards; on its medial surface is an oval facet for articulation with the transverse process of the first thoracic vertebra. At the tubercle the rib is bent, so that the head of the bone is directed slightly downwards. There is no angle. The *upper surface* of the body is marked by two shallow grooves, separated from each other by a slight ridge prolonged internally into the *scalene tubercle*, for the attachment of the *Scalenus anterior*; the groove in front of the tubercle transmits the subclavian vein, that behind the tubercle the subclavian artery and the lowest trunk of the brachial plexus.* In front of the anterior groove the *Subclavius* muscle takes origin, while behind the posterior groove is a rough area for the attachment of the *Scalenus medius*. The *under surface* is smooth, and destitute of a costal groove. The *outer border* is convex, thick and rounded behind, but thin in front. Immediately behind the subclavian groove it gives origin to the upper part of the first digitation of the *Serratus anterior*; the *inner border* is concave and thin, and marked near its centre by the *scalene tubercle*. The *anterior extremity* is larger and thicker than that of any of the other ribs.

* See article by Wood Jones, *Anat. Anzeiger*, Bd. xxxvi. 1910.

The second rib (fig. 283) is about twice the length of the first, but has a similar curvature. The non-articular portion of the *tubercle* is often small. The *angle* is slight, and situated close to the tubercle. The *body* is not twisted, so that both ends of it touch any plane surface upon which it may be laid; but at the tubercle there is an upward convexity, similar to, but smaller than, that found in the first rib. The *external surface* of the body is convex, and looks upwards and a little outwards; near its middle is a rough eminence for the origin of the lower part of the first and the whole of the second digitation of the *Serratus anterior*; behind and above this the *Scalenus posterior* is inserted. The *internal surface*, smooth and concave, is directed downwards and a little inwards; on its posterior part there is a short costal groove.

The tenth rib (fig. 284) has only a single articular facet on its head.

The eleventh and twelfth ribs (figs. 285 and 286) have each a single articular facet on the head, which is of rather large size; they have no necks or tubercles, and are pointed at their anterior ends. The eleventh has a slight

angle and a shallow costal groove. The twelfth has neither; it is much shorter than the eleventh, and its head is inclined slightly downwards. Sometimes the twelfth rib is shorter than the first.

Structure.—The ribs consist of highly vascular spongy substance enclosed in a thin layer of compact bone.

Ossification.—Each rib, with the exception of the first and the last two, is ossified from four centres; a primary centre for the body, and three secondary centres, one for the head and one each for the articular and non-articular parts of the tubercle.* The first rib has three centres, viz.: a primary one for the body, a secondary centre for the head, and one for the tubercle. The eleventh and twelfth ribs, being destitute of tubercles, have each only two centres. Ossification begins near the angle towards the end of the second month of foetal life, and is seen first in the sixth and seventh ribs. The epiphyses for the head and tubercle make their appearance between the sixteenth and twentieth years, and are united to the body about the twenty-fifth year.

THE COSTAL CARTILAGES

The costal cartilages (fig. 275) are bars of hyaline cartilage which extend forwards from the anterior ends of the ribs and contribute very materially to the elasticity of the walls of the thorax. The first seven pairs are connected

* Fawcett (*Journal of Anatomy and Physiology*, vol. xiv.) states that 'in all probability there is usually no epiphysis on the non-articular part of the tuberosity below the sixth or seventh rib.'

with the sternum; the eighth, ninth, and tenth are each articulated with the lower border of the cartilage immediately above; the last two have pointed extremities which end in the wall of the abdomen. The costal cartilages vary in their length, breadth, and direction. They increase in length from the first to the seventh, then gradually decrease to the twelfth. Their breadth, and the intervals between them, diminish from the first to the last. They are broad at their attachments to the ribs, and taper towards their sternal extremities, excepting the first and second, which are of the same breadth throughout, and the sixth, seventh, and eighth, which are enlarged where their margins are in contact. The first cartilage descends a little, the second is horizontal, the third ascends slightly, while the others are angular, following the course of the ribs for a short distance, and then ascending to the sternum or preceding cartilage.

Each costal cartilage has two surfaces, two borders, and two extremities. The *anterior surface* is convex, and looks forwards and upwards: that of the first gives attachment to the costoclavicular ligament and the Subclavius muscle; those of the first six or seven at their sternal ends, to the Pectoralis major. The others are covered by, and give partial attachment to, some of the flat muscles of the abdomen. The *posterior surface* is concave, and directed backwards and downwards; that of the first gives attachment to the Sternothyroideus, those of the third to the sixth inclusive to the Transversus thoracis, and the six inferior ones to the Transversus abdominis and the Diaphragm. The *superior border* is concave, the *inferior* convex; they afford attachment to the Intercostales interni. The inferior borders of the sixth, seventh, eighth, and ninth cartilages present heel-like projections at the points of greatest convexity; a similar heel-like projection occurs on the lower border of the fifth right cartilage in 72 per cent. and on the fifth left cartilage in 50 per cent. (Fawcett). On these projections are oblong facets which articulate respectively with facets on slight projections from the superior borders of the sixth, seventh, eighth, ninth, and tenth cartilages. The *lateral end* of each cartilage is continuous with the osseous tissue of the rib to which it belongs. The *medial end* of the first is continuous with the sternum: the medial ends of the six succeeding ones are rounded and articulate with shallow concavities on the lateral margins of the sternum. The medial ends of the eighth, ninth, and tenth costal cartilages are pointed, and each is connected with the cartilage immediately above. Those of the eleventh and twelfth are pointed and free. In old age the costal cartilages are prone to undergo superficial ossification.

THE THORAX

The skeleton of the thorax, or chest (fig. 287), is an osseocartilaginous cage, containing and protecting the principal organs of respiration and circulation. It is conical in shape, being narrow above and broad below, flattened from before backwards, and longer behind than in front. It is reniform on horizontal section on account of the forward projection of the vertebral bodies.

Boundaries.—*Posteriorly* it is formed by the twelve thoracic vertebrae and the posterior parts of the ribs. On either side of the vertebral column is a deep groove in consequence of the lateral and backward direction which the ribs take from their vertebral extremities to their angles. *Anteriorly* it is formed by the sternum and costal cartilages, and this surface is flattened or slightly convex. *Laterally* it is convex, and is formed by the ribs. The ribs and costal cartilages are separated from each other by the intercostal spaces, eleven in number, which are occupied by the Intercostal muscles and membranes.

The *upper opening* of the thorax is reniform in shape; its anteroposterior diameter is about 5 cm., its transverse about 10 cm. It slopes downwards and forwards, and is bounded by the first thoracic vertebra behind, the superior border of the manubrium sterni in front, and the first rib on either side. The *lower opening* is bounded by the twelfth thoracic vertebra behind, by the eleventh and twelfth ribs at the sides, and in front by the cartilages of the

tenth, ninth, eighth, and seventh ribs, which ascend on either side and form an angle, the *subcostal angle*, into the apex of which the xiphoid process projects. The lower opening is wider transversely than from before backwards, and slopes obliquely downwards and backwards; it is closed by the Diaphragm which forms the floor of the thorax.

The thorax of the female differs from that of the male as follows: 1. Its capacity is less. 2. The sternum is shorter. 3. The upper margin of the sternum is on a level with the lower part of the body of the third thoracic vertebra, whereas in the male it is on a level with the lower part of the body of the second. 4. The upper ribs are more movable, and so allow a greater expansion of the upper part of the thorax.

FIG. 287.—Front view of the skeleton of the thorax.

Applied Anatomy.—Fracture of the sternum is by no means common, owing, no doubt, to the elasticity of the ribs and their cartilages, which support it like so many springs. The fracture usually occurs in the upper half of the body. Dislocation of the body from the manubrium may take place, and is sometimes described as a fracture.

The bone is frequently the seat of gummatous tumours, and not uncommonly is affected with caries.

The ribs are frequently broken, though from their connexions and shape they are able to withstand great force, yielding under the injury and recovering themselves like a spring. The middle ribs are the most liable to fracture. The first, and to a less extent the second, being protected by the clavicle, are rarely fractured; and the eleventh and twelfth on account of their loose and floating condition enjoy a like immunity. The fracture generally occurs from indirect violence from forcible compression of the chest walls, and the bone then gives way at its weakest part, i.e. just in front of the angle. But the ribs may also be broken by direct violence, in which case the bone is driven inwards at the point struck. Fracture of the ribs is frequently complicated with some injury to the viscera contained within the thorax or upper part of the abdominal cavity; this is most likely to occur in fractures from direct violence.

Fracture of the costal cartilages, or separation of the cartilages from the ribs, may also take place, though they are comparatively rare injuries. In workmen the pressure of tools may displace the xiphoid process inwards.

The ribs are frequently the seat of tuberculous disease, with the formation of a chronic abscess in the chest-wall. This may not immediately overlie the carious portion of rib, as the pus is often directed a considerable distance along the costal groove before appearing beneath the integument.

Resection of a portion of a rib is often required in order to give efficient drainage to an empyema; this is referred to in the description of the respiratory organs.

Cervical ribs derived from the seventh cervical vertebra (page 166) are of not infrequent occurrence, and are important clinically because they may give rise to obscure nervous or vascular symptoms. The cervical rib may be a mere epiphysis articulating only with the transverse process of the vertebra, but more commonly it consists of a defined head, neck and tubercle, with or without a body. It extends lateralwards, or forwards and lateralwards, into the posterior triangle of the neck, where it may terminate in a free end or may join the first thoracic rib, the first costal cartilage, or the sternum.* It varies much in shape, size, direction, and mobility. If it reach far enough forwards, part of the brachial plexus and the subclavian artery and vein cross over it, and are apt to suffer compression in so doing. Pressure on the artery may obstruct the circulation so much that arterial thrombosis results, causing gangrene of the finger-tips. Pressure on the nerves is commoner, and affects the eighth cervical and first thoracic nerves, causing paralysis of the muscles they supply and neuralgic pains and paræsthesia in the area of skin to which they are distributed: no oculosupillary changes are to be found. If these symptoms be severe, removal of the rib or as much of it as causes pressure on the vessels and nerves is called for. The operation is not free from difficulty, and has been followed by paralysis of the muscles and by subclavian aneurysm, due to injuries inflicted in the course of the operation.

The *thorax* is frequently found to be altered in shape in certain diseases.

In *rickets*, the ends of the ribs, where they join the costal cartilages, become enlarged, giving rise to the so-called 'rickety rosary,' which in mild cases is only found on the internal surface of the thorax. Lateral to these enlargements the softened ribs sink in, so as to present a groove passing downwards and lateralwards on either side of the sternum. This bone is forced forwards by the bending of the ribs, and the anteroposterior diameter of the chest is increased. The ribs affected are the second to the eighth, the lower ones being prevented from falling in by the presence of the liver, stomach, and spleen; and when the abdomen is distended, as it often is in rickets, the lower ribs may be pushed outwards, causing a transverse groove (Harrison's sulcus) just above the costal arch. This deformity or forward projection of the sternum, often asymmetrical, is known as 'pigeon-breast,' and may be taken as evidence of active or old rickets except in cases of primary spinal curvature. In many instances it is associated in children with obstruction in the upper air-passages, due to enlarged tonsils or adenoid growths. In some rickety children or adults, and also in others who give no history or further evidence of having had rickets, an opposite condition obtains. The lower part of the sternum and often the xiphoid process as well are deeply depressed backwards, producing an oval hollow in the lower sternal and upper epigastric regions. This is known as 'funnel-breast' (German, *Trichterbrust*); it never appears to produce the least disturbance of any of the vital functions. The *phthisical chest* is often long and narrow, with great obliquity of the ribs and projection of the scapulæ. In *pulmonary emphysema* the chest is enlarged in all its diameters, and presents on section an almost circular outline. It has received the name of the 'barrel-shaped chest.' In severe cases of *lateral curvature of the vertebral column* the thorax becomes much distorted. In consequence of the rotation of the bodies of the vertebrae which takes place in this disease, the ribs opposite the convexity of the dorsal curve become extremely convex behind, being thrown out and bulging, and at the same time flattened in front, so that the two ends of the same rib are almost parallel. Coincidentally with this the ribs on the opposite side, on the concavity of the curve, are sunk and depressed behind, and bulging and convex in front.

It is commonly said that in tuberculosis of the lungs the chest is characteristically 'flat,' that is to say, that the ratio of its anteroposterior to its transverse diameter is less than the normal. But by careful measurement in a large number of cases, Woods Hutchinson has shown that this is not so. Taking the transverse diameter of the chest at the nipple level as =100, he finds that in the normal adult man between the ages of 20 and 44 the anteroposterior diameter =71. In 82 phthisical subjects it was =79·5, and in 30 'flat-chested' persons was =80. He explains the error as an optical illusion, due to rolling forwards of the shoulders in the 'flat-chested'; the back is seen to be correspondingly rounded and protuberant, while the forward position of the shoulders and clavicles lends an appearance of flattening to the chest.

More or less shrinkage of one side of the thorax is often seen as a consequence of adhesive pleurisy, in which the pulmonary and parietal pleura adhere closely to one another and the lung becomes collapsed and fibrosed. If this process be at all complete, great deformity of the chest results, the ribs on the affected side falling in, together with obliteration of the intercostal spaces; the contents of the mediastinal cavity are pulled over towards the affected side, and the other lung becomes emphysematous compensatory. The vertebral column becomes scoliotic, with the concavity of the curve towards the affected side.

* W. Thorburn, *The Med. Chronicle*, Manchester, 4th series, xiv. 1907.

THE SKULL

The skull is supported on the top of the vertebral column, and is of an ovoid shape, wider behind than in front. It is composed of a series of flattened or irregular bones which, with the exception of the mandible, are immovably jointed together. It is divisible into : (1) the *cranium*, which consists of fifteen bones, and (2) the *skeleton of the face*, which consists of seven, as follows :

	(Cranium, 15 bones	Occipital. Sphenoidal. Two Temporals. Two Parietals. Frontal. Ethmoidal. Two Inferior Nasal Conchæ. Two Lacrimals. Two Nasals. Vomer. Two Maxillæ. Two Palatines. Two Zygomatics. Mandible.
Skull, 22 bones		
	Face, 7 bones	

The hyoid bone, situated at the root of the tongue and attached to the base of the skull by ligaments, is described in this section.

CRANIAL BONES (OSSA CRANII)

THE OCCIPITAL BONE (OS OCCIPITALE)

The occipital bone (figs. 288, 289), situated at the posterior and inferior part of the cranium, is trapezoid in shape and concave forwards. It is pierced by a large oval aperture, the *foramen magnum*, through which the cranial cavity communicates with the vertebral canal. The expanded plate above and behind this foramen is named the *squama* ; the thick, somewhat quadrilateral piece in front of it is called the *basilar part* ; whilst on either side of it is the *lateral portion*.

The *squama*, situated above and behind the foramen magnum, is curved from above downwards and from side to side.

The *external surface* is convex and presents midway between the summit of the bone and the foramen magnum a prominence, the *external occipital protuberance*. Extending lateralwards from this on either side are two curved lines, one a little above the other. The upper, often faintly marked, is named the *highest nuchal line* (linea nuchæ suprema), and to it the galea aponeurotica (epicranial aponeurosis) is attached. The lower is termed the *superior nuchal line*. The part of the external surface above the highest nuchal lines is named the *planum occipitale* ; it is smooth, and covered by the Occipitalis muscle ; the part below, termed the *planum nuchale*, is rough and irregular for the attachment of several muscles. From the external occipital protuberance a ridge, the *median nuchal line*, often faintly marked, descends to the foramen magnum, and affords attachment to the ligamentum nuchæ ; running lateralwards from the middle of this line on either side is the *inferior nuchal line*. Several muscles (fig. 288) are attached to the outer surface of the squama, thus : the superior nuchal line gives origin to the Occipitalis and Trapezius, and insertion to the Sternocleidomastoideus and Splenius capitis ; into the surface between the superior and inferior nuchal lines the Semispinalis capitis and the Obliquus capitis superior are inserted ; the inferior nuchal line and the area below it receive the insertions of the Recti capitis posteriores major and minor. The posterior atlanto-occipital membrane is attached around the

posterolateral part of the foramen magnum, just outside the margin of the foramen.

The *internal surface* is deeply concave and divided into four fossæ by a *cruciate eminence*. The upper two fossæ are triangular, and lodge the posterior parts of the occipital lobes of the cerebrum; the lower two are quadrilateral and support the hemispheres of the cerebellum. At the point of intersection of the four divisions of the cruciate eminence is the *internal occipital protuberance*. The upper division of the median part of the cruciate eminence runs from this protuberance to the superior angle of the bone, and on one side of it (generally the right) is a wide groove, the *sagittal sulcus*, which lodges the hinder part of the superior sagittal sinus; to the margins of this sulcus the posterior part of the *falx cerebri* is attached. The lower division of the median part of the

FIG. 288.—Occipital bone. External surface.

cruciate eminence is prominent, and is named the *internal occipital crest*; it gives attachment to the *falx cerebelli*, and bifurcates near the foramen magnum; in the attached margin of this falx is the *occipital sinus*, which is sometimes duplicated. At the lower part of the internal occipital crest, a small depression is sometimes distinguishable; it is termed the *vernian fossa*, since it is occupied by part of the vermis of the cerebellum. *Transverse sulci*, one on either side, extend lateralwards from the internal occipital protuberance; they accommodate the transverse sinuses, and their margins give attachment to the *tentorium cerebelli*. The right transverse sulcus is usually larger than the left, and continuous with the sagittal sulcus; but the left may be larger than the right, or the two may be almost equal in size. The angle of union of the superior sagittal and transverse sinuses is named the *confluence of the sinuses* or *torcular Herophili*,* and its position is indicated by a depression on one or other side of the protuberance.

*Columns of blood coming in different directions were supposed to be pressed together at this point (*torcular*, a wine-press).

The *superior angle* of the squama articulates with the occipital angles of the parietal bones, and, in the foetal skull, corresponds in position with the *occipital fonticulus* (posterior fontanelle). The *lateral angles* are at the extremities of the transverse sulci; each is received into the interval between the mastoid angle of the parietal and the mastoid part of the temporal. The *lambdoidal* or *superior borders* extend from the superior to the lateral angles; they are serrated for articulation with the occipital borders of the parietal bones, and form by this union the lambdoidal suture. The *mastoid* or *inferior borders* extend from the lateral angles to the jugular processes; each articulates with the mastoid process of the corresponding temporal bone.

FIG. 289.—Occipital bone. Internal surface.

Superior Angle

The lateral parts are situated at the sides of the foramen magnum ; on their *inferior surfaces* are two oval processes named the *occipital condyles* for articulation with the superior facets of the atlas or first cervical vertebra. The condyles are oval or reniform in shape, with their long axes running forwards and medialwards, so that their anterior extremities are closer together than their posterior, and encroach on the basilar portion of the bone ; the posterior extremities extend back to the level of the middle of the foramen magnum. The articular surfaces of the condyles are convex from before backwards and from side to side ; they look downwards and lateralwards, and are occasionally constricted near their centres. On the medial side of each is a rough impression or tubercle for the alar ligament. Above the anterior part of either condyle is the *hypoglossal canal* (anterior condyloid foramen) ; this begins on the cranial surface of the bone a short distance above the anterior part of the foramen magnum, and is directed lateralwards and forwards. It may be partially or completely divided into two by a spicule of bone ; it gives exit to the hypoglossal nerve and entrance to a meningeal branch of the ascending pharyngeal

artery. Behind either condyle is a depression, the *condyloid fossa*, which receives the posterior margin of the corresponding superior facet of the atlas when the head is bent backwards; the floor of this fossa is sometimes perforated by the *condyloid canal*, through which an emissary vein passes from the transverse sinus. Extending lateralwards from the posterior half of the condyle is the *jugular process*, a quadrilateral plate of bone, indented in front by the *jugular notch* which, in the articulated skull, forms the posterior part of the jugular foramen. The jugular notch may be divided into two by a bony spicule, the *intrajugular process*, which projects forwards and lateralwards. The under surface of the jugular process is rough, and gives attachment to the Rectus capitis lateralis muscle; from this surface an eminence, the *paramastoid process*, sometimes projects downwards, and may be of sufficient length to articulate with the transverse process of the atlas. Laterally the jugular process presents a rough quadrilateral or triangular area which is joined to the

jugular surface of the temporal bone by a plate of cartilage; after the age of twenty-five this plate tends to ossify.

On the *upper surface* of the lateral part is an oval eminence, the *tuberculum jugulare*, which overlies the hypoglossal canal; it is crossed by the glossopharyngeal, vagus, and accessory nerves. On the upper surface of the jugular process is a deep groove which curves medialwards and forwards and is continuous with the jugular notch. This groove lodges the terminal part of the transverse sinus, and, close to its medial margin, the condyloid canal opens into it.

The *basilar part* extends forwards and upwards from the foramen magnum and presents *in front* an area more or less quadrilateral in outline. In the young skull this area is rough and uneven, and is joined to the body of the sphenoidal bone by a plate of cartilage. By the twenty-fifth year

FIG. 290.—Occipital bone at birth.

this plate of cartilage has undergone ossification, and the occipital and sphenoidal bones are fused.

On its *lower surface*, about 1 cm. in front of the foramen magnum, is the *pharyngeal tubercle* which gives attachment to the fibrous raphe of the pharynx. On either side of the middle line the Longus capitis and Rectus capitis anterior are inserted, and immediately in front of the foramen magnum the *anterior atlanto-occipital membrane* is attached.

The *upper surface* consists of a broad, shallow groove which inclines upwards and forwards from the anterior border of the foramen magnum; it supports the medulla oblongata and lower part of the pons, and near the margin of the foramen gives attachment to the membrana tectoria. On the lateral margins of this surface are the *inferior petrosal sulci* for the inferior petrosal sinuses, and below each of these sulci the lateral margin of the basilar part is rough for articulation with the petrous part of the temporal bone.

The *foramen magnum* is a large oval aperture with its long diameter anteroposteriorly; it is wider behind than in front, where it is encroached upon by the occipital condyles. It transmits the medulla oblongata and its membranes, the spinal portions of the accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, the membrana tectoria, and the alar ligaments.

Structure.—The occipital, like the other cranial bones, consists of two compact lamellæ, called the *outer and inner tables*, between which is the spongy substance or *diploë*; the bone is especially thick at the ridges, protuberances, condyles, and anterior portion of the basilar part; in the lower parts of the inferior fossæ it is thin, semitransparent, and destitute of diploë.

Ossification (fig. 290).—The upper part of the squama, i.e. the part above the

highest nuchal line, is developed in membrane, and is ossified from two centres (Mall),* one appearing on either side of the middle line about the second month of foetal life; it may remain separate throughout life, when it constitutes the *interparietal bone*. The rest of the bone is developed in cartilage. The lower part of the squama is ossified from two centres, which appear about the seventh week of foetal life and soon unite to form a single piece. Union of the upper and lower portions of the squama takes place in the third month of foetal life. An occasional centre appears in the posterior margin of the foramen magnum about the sixteenth week (Kerckring); this forms a separate ossicle (sometimes double) which unites with the rest of the squama before birth. Each of the lateral parts begins to ossify from a single centre during the eighth week of foetal life. The basilar portion is ossified from one centre (Mall), which appears about the sixth week of foetal life. About the fourth year the squama and the two lateral portions unite, and about the sixth year the bone consists of a single piece. Between the eighteenth and twenty-fifth years the occipital and sphenoidal bones unite to form a single bone.

THE SPHENOIDAL BONE (OS SPHENOIDALE)

The **sphenoidal bone** (figs. 291 to 293) is situated at the base of the skull in front of the temporals and the basilar part of the occipital. It somewhat resembles a bat with its wings extended, and consists of a central portion or

FIG. 291.—Sphenoidal bone. Superior surface.

body, two great and two small wings extending lateralwards from the sides of the body, and two pterygoid processes which are directed downwards from the adjoining parts of the body and great wings.

The **body**, more or less cubical in shape, contains two large cavities, the *sphenoidal air-sinuses*, separated from each other by a septum.

The **cerebral or superior surface** of the body (fig. 291) presents in front the *ethmoidal spine*, for articulation with the lamina cribrosa of the ethmoidal bone: behind this is a smooth surface faintly grooved on either side of the middle line, for the olfactory tracts of the brain. This surface is bounded behind by a ridge, which forms the anterior border of a transverse groove, the *sulcus chiasmatis* (optic groove); this sulcus ends on either side in the *optic foramen*. Posterior to the sulcus is a more or less oval elevation, the *tuberculum sellae*; and behind this is a deep depression, the *sella turcica*, the deepest part of which lodges the hypophysis cerebri and is known as the *fossa hypophyseos*. The anterior boundary of the *sella turcica* is completed laterally by two small eminences, called the *middle clinoid processes*, whilst the posterior boundary

* *American Journal of Anatomy*, vol. v. 1906.

is formed by a square-shaped plate of bone, the *dorsum sellæ*, the superior angles of which end in two tubercles, the *posterior clinoid processes*; these processes vary considerably in form and size, and give attachment to the lateral borders of the tentorium cerebelli. On either side of the dorsum sellæ is a notch for the passage of the abducent nerve, and below this notch a sharp process, the *petrosal process*, which articulates with the apex of the petrous portion of the temporal bone. Behind the dorsum sellæ is a shallow depression, which slopes obliquely backwards, and is continuous with the upper surface of the basilar portion of the occipital bone; it supports the upper part of the pons.

The lateral surfaces of the body are united with the great wings and with the medial pterygoid laminae. Above the attachment of each wing is a broad groove, the *carotid sulcus*, curved somewhat like the italic letter *f*; it lodges

FIG. 292.—Sphenoidal bone. Superior and posterior surfaces.

the internal carotid artery and the cavernous sinus. The carotid sulcus is deepest at the posterior part of the body where it is overhung by the petrosal process, and limited anterolaterally by a sharp margin which is called the *lingula*; the latter overlies the posterior opening of the pterygoid canal.

The posterior surface, quadrilateral in form (fig. 292), is joined, during infancy and adolescence, to the basilar part of the occipital bone by a plate of cartilage which becomes ossified between the eighteenth and twenty-fifth years.

The anterior surface of the body (fig. 293) presents, in the middle line, a triangular crest, the *sphenoidal crest*, which forms a small part of the septum of the nose; its anterior border articulates with the lamina perpendicularis of the ethmoidal bone; its lower, with the vomer. On either side of the crest is an opening leading into the corresponding *sphenoidal air sinus*.* These sinuses are two large, irregular cavities in the body of the bone, separated from one another by a bony septum, which is commonly bent to one or the other side. They vary considerably in form and size,† are seldom symmetrical, and

* Some confusion is occasioned to students commencing the study of anatomy by the name 'sinus' having been given to two different kinds of spaces connected with the skull. It may be as well, therefore, to state here that the 'sinuses' in the interior of the cranium which produce the grooves on the inner surfaces of the bones are venous channels which convey the blood from the brain, while the 'sinuses' external to the cranial cavity (the frontal, sphenoidal, ethmoidal, and maxillary) are hollow spaces in the bones themselves; they communicate with the nasal cavities, and contain air.

† Logan Turner (*The Accessory Sinuses of the Nose*, 1901) gives the following measurements for a sinus of average size: height, 2 cm.; breadth, 1.8 cm.; anteroposterior depth, 2.1 cm. Onodi (*The Accessory Sinuses of the Nose in Children*, 1911) states that in the new-born infant their height is 4 mm. and their width 2 mm., and that at the eighth year their height is from 8 to 12 mm. and their width 11 mm.

are often partially subdivided by bony laminae. A lateral recess may extend from one or other sinus into the great wing and lingula,* while occasionally they reach into the basilar part of the occipital bone nearly as far as the foramen magnum. In the articulated skull they are closed, in front and below, by the *sphenoidal conchæ* (see p. 201), only a round opening being left in the anterior wall of each sinus by which it communicates with the upper and posterior part of the nasal cavity and occasionally with the posterior ethmoidal air-cells. Each half of the anterior surface consists of two parts: (a) an upper and lateral depressed area which completes, with the labyrinth of the ethmoidal bone, the posterior ethmoidal cells; its lateral margin articulates with the lamina papyracea of the ethmoidal bone above, and with the orbital process of the palatine bone below; (b) a lower and medial, triangular, area which is smooth and forms the posterior part of the roof of the nose; near its superior angle is the round orifice of the sphenoidal sinus.

FIG. 293.—Sphenoidal bone. Anterior and inferior surfaces.

The *inferior surface* (fig. 293) presents, in the middle line, a triangular spine, the *sphenoidal rostrum*, which, in the articulated skull, projects into a deep fissure between the anterior parts of the alæ of the vomer. The posterior, triangular parts of the sphenoidal conchæ extend backwards on the sides of the rostrum, and articulate with the alæ of the vomer. On either side of the posterior part of the rostrum, and immediately behind the apex of the sphenoidal concha, is a projecting lamina, the *vaginal process*, directed medialwards from the base of the medial pterygoid lamina, with which it will be described.

The *great wings* (alæ magnæ) are two strong processes of bone, which curve upwards and lateralwards from the sides of the body. The posterior part of each is triangular and fits into the angle between the squama and the petrous portion of the temporal bone; projecting downwards from the apex of this triangular portion is a pointed process named the *spina angularis*, on the medial side of which there is usually a groove, directed downwards and forwards, for the chorda tympani nerve.† To the spina angularis are attached the sphenomandibular ligament and a part of the Tensor veli palatini.

* V. Z. Cope (*Journal of Anatomy and Physiology*, vol. li. part ii.) found a well-marked lateral recess in 72 out of 292 sinuses examined, and has pointed out that the hypophysis, the anterior part of the internal carotid artery, the optic and maxillary nerves, and the nerve of the pterygoid canal may give rise to elevations in the walls of the sinuses.

† B. Clements Lucas, *Proceedings of the Anatomical Society of Great Britain and Ireland*, November, 1894.

The *cerebral* or *superior surface* of the great wing (fig. 291) forms part of the floor of the middle fossa of the skull; it is deeply concave, and presents depressions corresponding with the convolutions of the anterior part of the temporal lobe of the brain. At its antero-medial part is a circular aperture, the *foramen rotundum*, for the passage of the *maxillary nerve*. Behind and lateral to this foramen is the *foramen ovale*, for the transmission of the *mandibular nerve*, the *accessory meningeal artery*, and sometimes the lesser *superficial petrosal nerve*.^{*} Medial to the foramen ovale, a small aperture, the *foramen Vesalii*, is sometimes seen; when present it opens below at the lateral side of the scaphoid fossa, and transmits a small vein from the cavernous sinus. In the posterior angle, near to but in front of the spina angularis, is a short canal, the *foramen spinosum*, which transmits the *nervus spinosus* and the middle meningeal artery.

The *lateral surface* (fig. 293) is convex, and divided by a transverse ridge, the *infratemporal crest*, into an upper or temporal and a lower or infratemporal surface. The *temporal surface*, concave from before backwards, forms a part of the temporal fossa, and gives origin to the Temporalis. The *infratemporal surface* is concave and directed downwards; it forms a part of the infratemporal fossa, and, together with the infratemporal crest, gives origin to the Pterygoideus externus. It is pierced by the foramen ovale and foramen spinosum, and at its posterior part is the spina angularis. Medial to the anterior extremity of the infratemporal crest is a triangular process which serves to increase the attachment of the Pterygoideus externus; a ridge extends downwards and medialwards from this process on to the front of the lateral pterygoid lamina; it forms the anterior limit of the infratemporal surface, and, in the articulated skull, the posterior boundary of the pterygomaxillary fissure.

The *orbital surface* of the great wing (fig. 293), quadrilateral in shape, is directed forwards and medialwards and forms the posterior part of the lateral wall of the orbit. Its upper serrated edge articulates with the orbital plate of the frontal bone; its lateral serrated margin with the zygomatic bone. Its inferior smooth border forms the posterolateral boundary of the inferior orbital fissure. Its medial sharp margin forms the lower boundary of the superior orbital fissure; projecting from near the centre of this margin is a little tubercle which gives attachment to the inferior head of the Rectus lateralis oculi; at the upper end of the margin is a notch for the transmission of the recurrent meningeal branch of the lacrimal artery. Below the medial end of the superior orbital fissure is a grooved surface, which forms the posterior wall of the pterygopalatine fossa, and is pierced by the foramen rotundum.

Margin of great wing (fig. 291).—The portion which extends from the body to the spina angularis is irregular. Its medial half forms the anterior boundary of the *foramen lacerum*, and presents the posterior aperture of the pterygoid canal for the passage of the corresponding nerve and artery. Its lateral half articulates, by means of a synchondrosis, with the petrous portion of the temporal bone, and between the two bones, on the under surface of the skull, is a furrow, the *sulcus tubæ*, for the lodgment of the cartilaginous part of the auditory tube. Extending forwards from the spina angularis is the *squamosal margin*, a concave, serrated edge, bevelled at the expense of the inner surface below, and of the outer surface above, for articulation with the temporal squama. The tip of the great wing, or *parietal angle*, is bevelled at the expense of the inner surface, for articulation with the sphenoidal angle of the parietal bone. Medial to this is a triangular rough area, for articulation with the frontal bone; the medial angle of this area is continuous with the sharp edge which forms the lower boundary of the superior orbital fissure, and the anterior angle with the serrated margin for articulation with the zygomatic bone.

The small wings (*alæ parvæ*) are two triangular plates, which project laterally from the upper and anterior parts of the body, and end in sharp points (fig. 291). The *cerebral surface* of each is smooth, and supports part of the frontal lobe of the brain. The *inferior surface* forms the posterior part of the roof of the orbit, and the upper boundary of the *superior orbital fissure*; its posterior part overhangs the anterior part of the middle fossa of the skull. The *superior orbital fissure* is triangular in shape, and leads from the cavity

^{*} The lesser superficial petrosal nerve sometimes passes through a special canal (*canaliculus innominatus* of Arnold) situated medially to the foramen spinosum.

of the cranium into that of the orbit ; it is bounded medially by the body of the sphenoid ; above, by the small wing ; below, by the medial margin of the orbital surface of the great wing ; and is completed laterally, between the greater and lesser wings, by the frontal bone. It transmits to the orbital cavity the oculomotor, trochlear, and abducent nerves, the three branches of the ophthalmic division of the trigeminal nerve, some filaments from the cavernous plexus of the sympathetic, and the orbital branch of the middle meningeal artery ; and from the orbital cavity the recurrent branch from the lacrimal artery to the dura mater, and the ophthalmic veins. The *frontal or anterior border* is serrated for articulation with the posterior edge of the orbital plate of the frontal bone. The *posterior border* is smooth and is received into the lateral cerebral fissure ; the medial end of this border forms the *anterior clinoid process*, which gives attachment to the free border of the tentorium cerebelli. The anterior and middle clinoid processes are sometimes united by a spicule of bone, and when this occurs the end of the groove for the internal carotid artery is converted into a foramen (*caroticoclinoid*). The small wing is connected to the body by two roots, the upper thin and flat, the lower thick and triangular ; between these is the *optic foramen*, for the transmission of the optic nerve and ophthalmic artery to the orbital cavity.

The *pterygoid processes* (figs. 292, 293), one on either side, descend perpendicularly from the region where the body and great wings unite. Each process consists of a medial and a lateral lamina, the upper parts of which are fused anteriorly ; a vertical groove, the *pterygopalatine sulcus*, descends on the front of the line of fusion, and forms, in the articulated skull, the posterior wall of the pterygopalatine canal. The laminae are separated below by an angular cleft, the *pterygoid fissure*, the rough margins of which articulate with the pyramidal process of the palatine bone. The two laminae diverge behind and enclose between them the V-shaped *pterygoid fossa*, which contains the Pterygoideus internus and Tensor veli palatini. Above this fossa is a small, oval, shallow depression, the *sphenoidal fossa*, which gives origin to part of the Tensor veli palatini. The anterior surface of the pterygoid process is broad and triangular near its root, where it forms the posterior wall of the pterygopalatine fossa and presents the anterior orifice of the *pterygoid canal*.

The *lateral lamina* of the pterygoid process is broad, thin, and everted ; its *lateral surface* forms part of the medial wall of the intratemporal fossa, and gives origin to the lower head of the Pterygoideus externus ; its *medial surface* forms the lateral wall of the pterygoid fossa, and gives origin to the Pterygoideus internus.

The *medial lamina* of the pterygoid process is narrower and longer than the lateral ; it projects backwards, but curves lateralwards at its lower extremity into a hook-like process, the *pterygoid hamulus*, around which the tendon of the Tensor veli palatini glides. The *lateral surface* of this plate forms part of the pterygoid fossa, and the Tensor veli palatini lies against it ; the *medial surface* constitutes the lateral boundary of the choana or posterior aperture of the corresponding nasal cavity. Superiorly the medial lamina is prolonged on to the under surface of the body as a thin plate, named the *vaginal process*, which articulates anteriorly with the sphenoidal process of the palatine bone and medially with the ala of the vomer. On the under surface of the vaginal process is a *furrow*, which is converted into a canal by the sphenoidal process of the palatine bone, for the transmission of the pharyngeal branch of the internal maxillary artery and the pharyngeal nerve from the sphenopalatine ganglion. The *pharyngobasilar fascia* (pharyngeal aponeurosis) is attached to the entire length of the posterior edge of the medial lamina, and the Constrictor pharyngis superior takes origin from its lower third. At the upper end of the medial pterygoid lamina is a small pyramidal process named the *pterygoid tubercle*, and immediately above this tubercle is the posterior opening of the pterygoid canal. Projecting backwards from near the middle of the posterior edge of this lamina is an angular process, the *processus tubarius*, which supports the *pharyngeal end* of the auditory tube. The anterior margin of the lamina articulates with the posterior border of the vertical part of the palatine bone.

The *sphenoidal conchae* are two thin, curved plates, situated at the anterior and lower parts of the body of the sphenoidal bone ; the upper, *concave surface*

of each forms the anterior wall and the greater part of the floor of the corresponding sphenoidal sinus. They are usually more or less destroyed in the process of disarticulating the skull, but when seen *in situ*, each consists of an anterior, vertical, quadrilateral part and a posterior, horizontal, triangular part. The anterior, vertical portion consists of, (a) an upper and lateral, depressed area which completes the posterior ethmoidal cells and articulates below with the orbital process of the palatine bone; and (b) a medial and lower area, smooth and triangular, which forms part of the roof of the nasal cavity, and is perforated near its superior angle by a round opening through which the sphenoidal sinus communicates with the sphenoidal recess of the nasal cavity. The anterior, vertical portions of the two bones meet in the middle line, and are there continued backwards as the sphenoidal crest. The horizontal triangular portion of the concha forms a part of the roof of the nasal cavity, and completes the sphenopalatine foramen; its medial margin articulates with the rostrum of the sphenoidal bone, and with the ala of the vomer; the apex, directed backwards, lies medial to and above the vaginal process of the medial pterygoid lamina, and articulates with the posterior part of the ala of the vomer. A small portion of the sphenoidal concha sometimes appears in the medial wall of the orbit, between the lamina papyracea of the ethmoidal bone in front, the orbital plate of the palatine bone below, and the frontal bone above.

Ossification.—Until the seventh or eighth month of foetal life the body of the sphenoidal bone consists of two parts—viz. one in front of the tuberculum sellæ, the *presphenoidal part*, with which the small wings are continuous; the other comprising the sella turcica and dorsum sellæ, the *postsphenoidal part*, with which are associated the great wings, and pterygoid processes.

FIG. 294.—Sphenoidal bone at birth. Posterior aspect.

The greater part of the bone is ossified in cartilage. There are fourteen centres in all, six for the presphenoidal and eight for the postsphenoidal part.

Presphenoidal part. About the ninth week of foetal life an ossific centre appears for each of the small wings, just lateral to the optic foramen; shortly afterwards two nuclei appear in the presphenoidal part of the body. The sphenoidal conchæ are each de-

veloped from a centre which makes its appearance about the fifth month*; at birth they consist of small triangular laminae; about the third year they become hollowed out and cone-shaped; about the fourth year they fuse with the labyrinths of the ethmoidal bone, and between the ninth and twelfth years with the sphenoidal bone.

Postsphenoidal part.—The first ossific centres are those for the great wings. One appears below the foramen rotundum in the cartilage which forms the base of each wing about the eighth week; the orbital plate and that part of the sphenoidal bone which is found in the temporal fossa, as well as the lateral pterygoid lamina, are ossified in membrane.† About the fourth month, two centres appear in the postsphenoidal part of the body, one on either side of the sella turcica, and fuse about the middle of foetal life. Each medial pterygoid lamina (with the exception of its hamulus) is ossified in membrane, and its centre probably appears about the ninth or tenth week; the hamulus is chondrified during the third month, and almost at once begins to ossify (Fawcett‡). The medial and lateral pterygoid laminae join about the sixth month. About the fourth month a centre appears for each lingula and speedily joins the rest of the bone.

The presphenoidal and the postsphenoidal parts fuse about the eighth month of foetal life, and at birth the bone is in three pieces (fig. 294): a central, consisting

* According to Cleland, each sphenoidal concha is ossified from four centres.

† Fawcett, *Journal of Anatomy and Physiology*, vol. xlv, 1910.

‡ *Anatomischer Anzeiger*, March 1906.

of the body and small wings, and two lateral, each comprising a great wing and pterygoid process. In the first year after birth the great wings and body unite, and the small wings extend medialwards above the anterior part of the body, and meet to form an elevated smooth surface, termed the *jugum sphenoidale*. By the twenty-fifth year the sphenoidal and occipital bones are completely fused. In the anterior part of the fossa hypophyseos there are occasionally seen the remains of the *canalis craniopharyngeus*, through which, in early foetal life, the hypophysial diverticulum of the buccal ectoderm is transmitted (see page 132).

Traces of the sphenoidal sinuses are seen as early as the third month of foetal life, but the sinuses do not attain their full size until after puberty.

Certain parts of the sphenoidal bone are connected by ligaments which occasionally ossify. The more important of these ligaments are: the *pterygospinous*, stretching between the spina angularis and the upper part of the lateral pterygoid lamina (see *fascia colli*); the *interclinoid*, joining the anterior to the posterior clinoid process; and the *caroticoclinoid*, connecting the anterior to the middle clinoid process.

Applied Anatomy.—Premature ossification or synostosis of the intersphenoidal suture (which normally begins to join at birth) and of the sphenobasilar suture produces a characteristic physiognomy. This is best seen in profile, and consists in an abnormal depression of the bridge of the nose; it is a feature often observed in dwarfs.

THE TEMPORAL BONE. (OSSA TEMPORALIA)

The **temporal bones** are situated at the sides and base of the skull. Each consists of five parts, viz. the *squama*, the *petrous*, *mastoid*, and *tymppanic parts*, and the *styloid process*.

The **squama** forms the anterior and upper part of the bone, and is scale-like, thin and translucent. Its *temporal or external surface* (fig. 295) is smooth and slightly convex; it forms part of the temporal fossa and gives origin to the Temporalis muscle; on its hinder part, above the opening of the external acoustic meatus, is a vertical groove for the middle temporal artery. A curved line, the *temporal line* or *supramastoid crest*, runs backwards and upwards, across its posterior part; it serves for the attachment of the temporal fascia, and limits the origin of the Temporalis muscle. The boundary between the squama and the mastoid portion of the bone lies about a centimetre below this line, and is frequently indicated by traces of the original mastoid suture. Projecting from the lower part of the squama is a long, arched process, the *zygomatic process*. This process is attached by a broad base and is at first directed laterally, its surfaces looking upwards and downwards; it then twists inwards and runs forwards, its surfaces now looking medially and laterally. The superior border, long and thin, gives attachment to the temporal fascia; the inferior, short and arched, gives origin to some fibres of the Masseter. The lateral surface is convex and subcutaneous; the medial is concave, and gives origin to part of the Masseter. The anterior end is deeply serrated and cut obliquely at the expense of the lower border; it articulates with the zygomatic bone. The posterior end is connected to the squama by two roots—*anterior* and *posterior*. The posterior root, a prolongation of the upper border, runs backwards above the opening of the external acoustic meatus, and is continuous with the temporal line. Between the opening of the external acoustic meatus and the posterior root of the zygomatic process is the *supramental triangle* of Macewen, through which an instrument may be pushed into the tympanic antrum. The anterior root, continuous with the lower border, is short but broad and strong; it is directed medially and ends in an eminence, the *articular tubercle* (*eminentia articularis*). This tubercle is convex from before backwards, and forms the anterior boundary of the mandibular fossa. In front of it is a small triangular area which forms part of the infratemporal fossa, and is separated from the outer surface of the squama by a ridge which is continuous behind with the anterior root of the zygomatic process, and in front, in the articulated skull, with the infratemporal crest on the great wing of the sphenoidal bone. At the junction of the anterior root with the zygomatic process is a tubercle for the attachment of the temporomandibular ligament, and behind the anterior root is an oval depression, forming part of the mandibular fossa. The *mandibular fossa* (glenoid fossa) is bounded, in front, by

the articular tubercle ; it consists of an anterior, articular portion, formed by the squama, and a posterior non-articular portion, formed by the tympanic part of the bone. The articular portion, smooth, oval and deeply concave, articulates with the articular disc of the temporomandibular joint ; the non-articular portion sometimes lodges a small part of the parotid gland. A small, somewhat conical, eminence (postglenoid tubercle) separates the lateral half of the articular portion from the anterior margin of the tympanic part, and is the representative of a prominent tubercle which, in some mammals, descends behind the condyle of the mandible, and prevents its backward displacement. The medial half of the articular portion of the mandibular fossa is separated from the tympanic part of the bone by the lower edge of a plate which projects

FIG. 295.—Left temporal bone. External surface.

downwards from the tegmen tympani of the petrous part ; the fissure between this plate and the tympanic part is named the *petrotympanic fissure* (Glaserian fissure). The petrotympanic fissure leads into the middle ear or tympanic cavity ; it lodges the anterior process of the malleus, and transmits the anterior tympanic branch of the internal maxillary artery. The medial part of the fissure is known as the *canal of Huguier* ; it transmits the chorda tympani nerve.

The *cerebral* or *internal surface* of the squama (fig. 296) is concave ; it presents depressions corresponding to the convolutions of the temporal lobe of the brain, and grooves for the branches of the middle meningeal vessels ; its lower border is united to the anterior surface of the petrous portion by the *petrosquamous suture*, traces of which are frequently seen.

The *parietal* or *superior border* is thin, and bevelled at the expense of the internal surface ; it overlaps the squamous border of the parietal bone, forming with it the squamosal suture. Posteriorly, the superior border forms an angle, the *parietal notch*, with the mastoid portion of the bone. The *sphenoidal* or *antero-inferior border*, thin above and thick below, articulates with the great wing of the sphenoidal bone ; its upper part is bevelled at the expense of the inner surface, its lower at the expense of the outer surface.

The mastoid portion forms the posterior part of the bone. Its *outer surface* (fig. 295) is rough, and gives attachment to the Occipitalis and Auricularis posterior. It is frequently perforated near the posterior border by the *mastoid foramen* which transmits a vein from the transverse sinus and a small branch of the occipital artery to the dura mater; the position and size of this foramen are very variable; it may be situated in the occipital bone, or in the suture between the temporal and the occipital. The mastoid portion is continued below into a conical projection, the *mastoid process*, the size and form of which vary somewhat; it is larger in the male than in the female. This process serves for the attachment of the Sternocleidomastoideus, Splenius capitis, and Longissimus capitis; on its medial side is a deep groove, the *mastoid notch*

FIG. 296.—Left temporal bone. Internal surface.

(*digastric fossa*), for the attachment of the posterior belly of the Digastricus; medial to this notch is a shallow furrow, the *occipital groove*, which lodges the occipital artery.

On the *inner surface* of the mastoid portion is a deep, curved groove, the *sulcus sigmoideus*, which lodges part of the transverse sinus; in it may be seen the opening of the mastoid foramen. The sulcus sigmoideus is separated from the innermost of the mastoid air-cells by a thin lamina of bone which may be partly deficient.

The *superior border* of the mastoid portion is thick and serrated for articulation with the mastoid angle of the parietal bone. The *posterior border*, also serrated, articulates with the inferior border of the occipital bone between the lateral angle and jugular process. Anteriorly the mastoid portion is fused with the descending process of the squama above; below it enters into the formation of the external acoustic meatus and the tympanic cavity.

A section of the mastoid process (fig. 297) exhibits a number of spaces, the *mastoid cells*, which vary greatly in size and number. At the upper and front part of the process they are large and irregular and contain air, but towards the lower part they diminish in size, while those at the apex of the

process are frequently quite small ; occasionally they are entirely absent, and the mastoid is then solid throughout. In addition to the mastoid cells a large irregular cavity, the *tympanic antrum*, is situated in the upper and front part of the bone ; it is filled with air and lined by a prolongation of the mucous membrane of the tympanic cavity. It is bounded above by a thin plate of bone, the *tegmen tympani*, which separates it from the middle fossa of the base of the skull ; laterally by the squama just below the temporal line ; medial to it is the lateral semicircular canal of the internal ear which projects into its cavity ; below and behind, it communicates with the mastoid air-cells. It opens in front into that portion of the tympanic cavity which is known as the *attic* or *epitympanic recess*. The tympanic antrum is a cavity of some considerable size at the time of birth ; the mastoid air-cells originate as diverticula

FIG. 207.—Coronal section of right temporal bone.

from the antrum, and begin to appear at or before birth ; by the fifth year they are well marked, but their development is not completed until towards puberty.

The **petrous portion** or **pyramid** is wedged between the sphenoidal and occipital bones at the base of the skull. It is directed medialwards, forwards, and a little upwards, and has a base, an apex, three surfaces, and three angles ; the essential parts of the organs of hearing and equilibration are placed within it.

The **base** is fused with the squama and the mastoid portion.

The **apex**, rough and uneven, is received into the angular interval between the posterior border of the great wing of the sphenoidal bone and the basilar part of the occipital bone ; it is pierced by the anterior or internal orifice of the carotid canal, and forms the posterolateral boundary of the foramen lacerum.

The **anterior surface** forms the posterior part of the middle fossa of the skull, and is continuous with the inner surface of the squama, to which it is united by the *petrosquamous suture*, remains of which are distinct even at a late period of life. It is marked by depressions for the convolutions of the brain, and presents six points for examination : (1) near the centre is the *eminencia acuta* which indicates the situation of the superior semicircular canal ; (2) in front of and a little lateral to this eminence is a depressed area

which forms the roof of the tympanic cavity and consists of a thin plate of bone known as the *tegmen tympani*; a thin scale of this descends between the squama and the tympanic plate, and forms the anterior boundary of the petrotympanic fissure, and the greater part of the lateral wall of the semicanal for the *Tensor tympani* muscle; (3) a shallow groove, sometimes double, leads backwards and lateralwards to an oblique opening, the *hiatus of the facial canal*, for the passage of the greater superficial petrosal nerve and the petrosal branch of the middle meningeal artery; (4) lateral to the hiatus there is occasionally a smaller opening for the passage of the lesser superficial petrosal nerve; (5) near the apex of the bone is the termination of the carotid canal, the anterior wall of which is here deficient; (6) above this canal is the shallow *trigeminal impression* for the reception of the semilunar ganglion of the trigeminal nerve.

The *posterior surface* (fig. 296) forms the anterior part of the posterior fossa of the skull, and is continuous with the inner surface of the mastoid portion. Near the centre is an orifice of varying size, the *porus acusticus internus* leading into the *internal acoustic meatus*, a short canal, about 1 cm. in length, which runs lateralwards. It transmits the facial and acoustic nerves and the internal auditory branch of the basilar artery. The lateral end of the internal acoustic meatus is closed by a vertical plate which separates it from the internal ear. This plate is divided by a horizontal crest, the *crista transversa*, into two unequal portions, each of which (fig. 298) is subdivided by a vertical ridge into an anterior and a posterior part. In the portion beneath the *crista transversa* are three sets of foramina: one group, below the posterior part of the crest, and situated in the *area vestibularis inferior*, consists of several small openings for the transmission of the nerves to the sacculæ; below and behind this area is the *foramen singulare*, which gives passage to the nerve to the posterior semicircular duct; in front of and below the *area vestibularis inferior* is the *tractus spiralis foraminosus*, consisting of a number of small spirally arranged openings, which encircle the *canalis centralis cochleæ*; these openings together with the *canalis centralis cochleæ* transmit the nerves to the cochlea. The portion above the *crista transversa* displays behind, the *area vestibularis superior*, pierced by a series of small openings for the passage of the nerves to the utricle and the superior and lateral semicircular ducts, and, in front, the *area facialis*, with one large opening which is the commencement of the *canalis facialis* (aqueductus Fallopii) and transmits the facial nerve. Behind the *porus acusticus internus* is a small slit almost hidden by a thin plate of bone, leading to a canal, the *aqueductus vestibuli*, which contains the ductus endolymphaticus together with a small artery and vein. Above and between these two openings is an irregular depression which lodges a process of the dura mater and transmits a small vein; in the infant this depression is represented by a large fossa, the *fossa subarcuata*, which extends backwards as a short blind tunnel under the superior semicircular canal.

The *inferior surface* (fig. 299), rough and irregular, forms part of the external surface of the base of the skull. It presents the following parts for examination: (1) near the apex is a quadrilateral rough surface, which serves partly for the attachment of the *levator veli palatini* and the cartilaginous portion of the auditory tube, and partly for connexion with the basilar part of the occipital bone through the intervention of some dense fibrous tissue; (2) behind

FIG. 298.—Diagrammatic view of the lateral end of the right internal acoustic meatus. (Testut.)

1. Crista transversa. 2. Area facialis, with (2') internal opening of the facial canal. 3. Ridge separating the area facialis from the area vestibularis superior. 4. Area vestibularis superior, with (4') openings for nerve filaments. 5, 5'. Tractus spiralis foraminosus, and (5') the canalis centralis of the cochlea. 6. Ridge separating the tractus spiralis foraminosus from the area vestibularis inferior. 7. Area vestibularis inferior, with (7') orifices for nerves to sacculæ. 8. Foramen singulare.

this is the large, nearly circular aperture of the *carotid canal*; this canal at first is vertical, and then, making a bend, runs horizontally forwards and medialwards; it transmits into the cranium the internal carotid artery, and the carotid plexus of nerves; (3) behind these openings is a deep depression, the *jugular fossa*, of variable depth and size in different skulls; it lodges the bulb of the internal jugular vein; (4) in front of the medial part of the jugular fossa and directly below the internal acoustic meatus is a triangular depression; at the apex of this depression is a small opening, the *aquæductus cochleæ*, which lodges a tubular prolongation of the dura mater and transmits a vein from the cochlea to join the internal jugular vein; (5) in the bony ridge dividing the carotid canal from the jugular fossa is the small *inferior tympanic canaliculus* for the passage of the tympanic branch of the glossopharyngeal nerve (nerve

FIG. 299.—Left temporal bone. Inferior surface.

of Jacobson); (6) in the lateral part of the jugular fossa is the *mastoid canaliculus* for the entrance of the auricular branch of the vagus nerve (nerve of Arnold); (7) behind the jugular fossa is the *jugular surface*, a rough quadrilateral area covered with cartilage in the recent state, and articulating with the jugular process of the occipital bone; (8) extending lateralwards from the carotid canal is the sharp lower border of the tympanic part of the bone; the lateral part of this border splits to ensheath the root of the styloid process and is therefore named the *vagina processus styloidei*; (9) emerging from its sheath is the *styloid process*, which is about 2.5 cm. in length, and is directed downwards and forwards; (10) between the styloid and mastoid processes is the *stylomastoid foramen*; it is the termination of the facial canal, and transmits the facial nerve and stylomastoid artery.

The *superior angle* (superior margin), the longest, is grooved for the superior petrosal sinus, and gives attachment to the tentorium cerebelli; at its medial extremity is a shallow notch, in which the trigeminal nerve lies. The *posterior angle* (posterior margin) is intermediate in length between the superior and the anterior. Its medial part is marked by a sulcus, which forms, with a

corresponding sulcus on the occipital bone, the channel for the inferior petrosal sinus. Behind this is the *jugular fossa* which, with the jugular notch on the occipital bone, forms the jugular foramen; an eminence occasionally projects from the centre of the fossa, and divides the foramen into two. The *anterior angle* (anterior margin) is divided into two parts—a lateral, joined to the squama at the *petrosquamous suture*; a medial, free for articulation with the *spina angularis* of the sphenoidal bone.

At the angle of junction of the petrous part and the squama are two canals placed one above the other, and separated by a thin plate of bone, the *septum canalis musculotubarii* (*processus cochleariformis*). Both canals lead into the tympanic cavity; the upper (*semicanalis m. tensoris tympani*) transmits the Tensor tympani muscle, the lower (*semicanalis tubæ auditivæ*) forms the bony part of the auditory tube.

FIG. 300.—The three principal parts of the right temporal bone at birth.

1. Outer surface of petromastoid part. 2. Inner surface of tympanic ring. 3. Inner surface of squama.

The **tympanic part** is a curved plate of bone lying below the squama and in front of the mastoid process. Its *posterosuperior surface* is concave, and forms the anterior wall, the floor, and part of the posterior wall of the bony external acoustic meatus; at the medial end of this surface is a narrow furrow, the *tympanic sulcus*, for the attachment of the circumference of the tympanic membrane. Its *antero-inferior surface* is quadrilateral and slightly concave; it constitutes the posterior wall of the mandibular fossa, and is sometimes in contact with a part of the parotid gland. Its *lateral border* is free and rough, and gives attachment to the cartilaginous part of the external acoustic meatus. Internally, the tympanic part is fused with the petrous portion, and appears in the retreating angle between it and the squama, where it lies below and lateral to the orifice of the auditory tube. Posteriorly, it blends with the squama and mastoid part, and forms the anterior boundary of the tympanomastoid fissure. The lateral part of the *upper border* is fused with the back of the postglenoid process; its medial part forms the posterior boundary of the petrotympanic fissure. The medial part of the *lower border* is sharp; the lateral part splits to enclose the root of the styloid process, and is therefore named the *vagina processus styloidei*. The central portion of the tympanic part is thin, and in a considerable percentage of skulls is perforated by the *foramen of Huschke*.

The *external acoustic meatus*, nearly 2 cm. long, is directed inwards and slightly forwards and downwards, so that the floor of the meatus is convex upwards. In sagittal section it is oval or elliptical in shape with the long axis directed downwards and slightly backwards. Its anterior wall and floor and the lower part of its posterior wall are formed by the tympanic part of the bone; the roof and the upper part of the posterior wall by the squama. Its inner end is closed, in the recent state, by the tympanic membrane; its outer end (*porus*

acusticus externus) is bounded above by the posterior root of the zygomatic process, below which a small spine, the *supramental spine*, is sometimes seen at the upper and posterior part of the orifice.

The **styloid process**, slender, pointed, and averaging about 2.5 cm. in length, projects downwards and forwards, from the under surface of the temporal bone. Its proximal part (*tympanohyal*) is surrounded by its sheath (*vagina processus styloidei*), while its distal part (*stylohyal*) gives attachment to the stylohyoid and stylomandibular ligaments, and to the Styloglossus, Stylohyoideus and Stylopharyngeus muscles.

Structure.—The structure of the squama is like that of the other cranial bones : the mastoid portion is spongy, and the petrous portion dense and hard.

Ossification.—The temporal bone is ossified from eight centres (exclusive of those for the internal ear and the tympanic ossicles)—viz. one for the squama, one for the tympanic part, four for the petrous and mastoid parts, and two for the styloid process. Just before the close of foetal life the bone consists of three principal parts, viz. : the squama, the petromastoid part, and the tympanic ring (fig. 300). The *squama* is ossified in membrane from a single nucleus which appears near the root of the zygomatic process about the seventh or eighth week of foetal life. The *petromastoid* part is developed from four centres, which make their appearance in the cartilaginous ear-capsule (page 75) about the fifth or sixth month. One (*pro-otic*) appears in the neighbourhood of the eminentia arcuata, spreads in front of and above the internal acoustic meatus and extends to the apex of the bone ; it forms part of the cochlea, vestibule, superior semicircular canal, and medial wall of the tympanic cavity. A second (*opisthotic*) appears at the promontory on the medial wall of the tympanic cavity and surrounds the fenestra cochleæ ; it forms the floor of the tympanic cavity and vestibule, surrounds the carotid canal, invests the lateral and lower part of the cochlea, and spreads medially below the internal acoustic meatus. A third (*pterotic*) roofs in the tympanic cavity and antrum ; while the fourth (*epiotic*) appears near the posterior semicircular canal and extends to form the mastoid process (Vrolik). The *tympanic ring* is an incomplete circle in the concavity of which is a groove, the tympanic sulcus, for the attachment of the circumference of the tympanic membrane. This ring expands to form the

FIG. 301.—Temporal bone at birth. Outer aspect.

tympanic part, and is ossified in membrane from a single centre which appears about the third month.* The *styloid process* is developed from the proximal part of the cartilage of the second branchial or hyoid arch by two centres : one for the proximal part, the *tympanohyal*, appears before birth ; the other, comprising the rest of the process, is named the *stylohyal*, and does not appear until after birth. The tympanic ring unites with the squama shortly before birth ; the petromastoid part and the squama join

during the first year, and the tympanohyal portion of the styloid process about the same time (figs. 301, 302). The stylohyal does not unite with the rest of the bone until after puberty, and in some skulls never at all.

The chief subsequent changes in the temporal bone apart from increase in size are : (1) The tympanic ring extends lateralwards and backwards to form the tympanic part of the bone. This extension does not, however, take place at an equal rate all round the circumference of the ring, but occurs most rapidly on its anterior

* Two crests, the *superior* and *inferior tympanic crests*, run obliquely downwards and forwards across the anterior part of the inner surface of the tympanic ring. Between them is an obliquely directed furrow, the *sulcus malleolaris*, which lodges the anterior process of the malleus. The anterior tympanic artery and the chorda tympani nerve.

and posterior portions, and these outgrowths meet and blend, and thus, for a time, there exists in the floor of the meatus a foramen, the *foramen of Huschke*; this foramen is usually closed about the fifth year, but may persist throughout life. (2) The mandibular fossa is at first extremely shallow, and looks more lateralwards than downwards: it becomes deeper and is ultimately directed downwards. Its change in direction is accounted for as follows. The part of the squama which forms the fossa lies at first below the level of the zygomatic process and is nearly vertical, but in consequence of the subsequent increase in the width of the base of the skull this part of the squama comes to be directed horizontally inwards, and its surfaces therefore upwards and downwards; the attached portion of the zygomatic process also becomes everted and projects like a shelf at right angles to the squama. (3) The mastoid portion is at first quite flat, and the stylo-mastoid foramen and rudimentary styloid process lie immediately behind the tympanic ring. With the development of the mastoid air-cells the outer part of the mastoid portion grows downwards and forwards to form the mastoid process, and the styloid process and stylo-mastoid foramen come to lie on the under surface of the bone. The descent of the stylo-mastoid foramen is necessarily accompanied by a corresponding increase in the length of the facial canal. (4) The downward and forward growth of the mastoid process also pushes forward the tympanic part, so that the portion of the latter which formed the original floor of the meatus and contained the foramen of Huschke ultimately constitutes the anterior wall of the meatus. (5) The fossa subarcuata on the posterior surface of the petrous portion becomes filled up and almost obliterated.

FIG. 302.—Temporal bone at birth.
Inner aspect.

THE PARIETAL BONES (OSSA PARIETALIA)

The **parietal bones** form, by their union, the sides and roof of the cranium. Each is irregularly quadrilateral in shape, and has two surfaces, four borders, and four angles.

The *parietal* or *external surface* (fig. 303) is convex, smooth, and marked near the centre by an eminence, the *parietal tuberosity* or *eminence*. Crossing the middle of the bone in an arched direction are two curved lines, the *superior* and *inferior temporal lines*; the former gives attachment to the temporal fascia, and the latter indicates the upper limit of the origin of the Temporalis. Above these lines the bone is covered by the galea aponeurotica; below them it forms part of the temporal fossa. At the posterior part and close to the upper or sagittal border is the *parietal foramen*, which transmits a vein from the superior sagittal sinus, and sometimes a small branch of the occipital artery; the foramen is not constantly present, and its size varies considerably.

The *cerebral* or *internal surface* (fig. 304) is concave; it presents depressions corresponding to the cerebral convolutions, and numerous furrows for the ramifications of the middle meningeal vessels*; the latter run upwards and backwards from the sphenoidal angle, and from the central and posterior part of the squamous border. Along the upper or sagittal border is a shallow groove, which, with that on the opposite parietal, forms the *sagittal sulcus*, for the superior sagittal sinus; to the edges of the sulcus the falx cerebri is attached. Near the sulcus are several depressions, best marked in the skulls of old persons, for the arachnoidal granulations (*glandulae Pacchionii*).

* Consult articles by F. Wood Jones, *Journal of Anatomy and Physiology*, vol. xlvii, and B. Coen, *Journal of Anatomy and Physiology*, vol. xlviii.

The *sagittal border*, the longest and thickest, is dentated and articulates with its fellow of the opposite side, to form the sagittal suture. The *squamous border* is divided into three parts: of these, the anterior is thin and pointed, bevelled at the expense of the external surface, and overlapped by the tip of the great wing of the sphenoidal bone; the middle portion is arched, bevelled at the expense of the external surface, and overlapped by the squama of the temporal bone; the posterior part, thick and serrated, articulates with the mastoid portion of the temporal bone. The *frontal border* is deeply serrated,

FIG. 303.—Left parietal bone. External surface.

and bevelled at the expense of the external surface above and of the internal below; it articulates with the frontal bone, forming one half of the coronal suture. The *occipital border*, deeply dentated, articulates with the occipital bone, forming one half of the lambdoidal suture.

The *frontal angle* is practically a right angle, and corresponds with the point of meeting of the sagittal and coronal sutures; this point is named the *bregma*; in the foetus and for about a year and a half after birth this region of the skull is membranous, and is called the *frontal fonticulus* (anterior fontanelle). The *sphenoidal angle*, thin and acute, is received into the interval between the frontal bone and the great wing of the sphenoidal bone; in some cases the frontal bone articulates with the squama of the temporal bone, and the parietal then fails to reach the great wing of the sphenoidal bone. Its internal surface is marked by a deep groove, sometimes a canal, for the anterior divisions of the middle meningeal vessels. The *occipital angle* is rounded and corresponds with the *lambda* or point of meeting of the sagittal and lambdoidal sutures; in the foetus, and for about a year after birth, this part of the skull is membranous, and is called the *occipital fonticulus* (posterior fontanelle). The *mastoid angle*

is blunt and articulates with the occipital bone and with the mastoid portion of the temporal bone; on its internal surface is a broad, shallow groove, the transverse sulcus, which lodges a small part of the transverse sinus.

Ossification.—The parietal bone is ossified in membrane from two centres, which appear one above the other at the parietal tuberosity about the seventh week of foetal life. These centres unite early, and ossification gradually extends in a radial manner towards the margins of the bone; the angles are consequently the parts last formed, and it is here that the fonticuli exist. At birth the temporal

FIG. 304.—Left parietal bone. Internal surface.

lines are situated low down; they only reach their permanent position after the eruption of the molar teeth. Occasionally the parietal bone is divided into two parts, upper and lower, by an anteroposterior suture.

THE FRONTAL BONE (OS FRONTALE)

The frontal bone resembles a cockle-shell in form, and consists of two portions—a vertical part, the *squama*, corresponding with the region of the forehead; and a horizontal or *orbital* part, which enters into the formation of the roofs of the orbital and nasal cavities.

Squama.—The *external surface* of the squama (fig. 305) is convex and divided into a large frontal and two small temporal surfaces by lines which arch backwards across the lateral parts of the bone.

The *frontal surface* usually exhibits, in the lower part of the middle line, the remains of the *frontal* or *metopic suture*; in infancy this suture divides the bone into two, a condition which persists in about 9 per cent. of skulls. On either side of this suture, about 3 cm. above the supraorbital margin, is a rounded elevation, the *frontal tuberosity* or *eminence*. These tuberosities vary in size in different individuals, are occasionally unsymmetrical, and are especially prominent in young skulls; the surface of the bone above them is smooth, and covered by the *galea aponeurotica*. Below the frontal tuberosities, and separated from them by a shallow groove, are two curved elevations, the

superciliary arches, the medial parts of which are prominent, and joined to one another by a smooth elevation named the *glabella*. These arches are larger in the male than in the female, and their degree of prominence depends to some extent on the size of the frontal air-sinuses; prominent ridges are, however, occasionally associated with small air-sinuses. Beneath the superciliary arches are the curved *supraorbital margins*, which form the upper boundaries of the bases of the orbits, and separate the squama from the orbital portion of the bone. The lateral two-thirds of each supraorbital margin are sharp; the medial third is rounded. At the junction of these two parts is the *supraorbital notch* or *foramen* which transmits the supraorbital vessels and nerve. Medial

FIG. 305.—Frontal bone. External surface.

to this foramen is the small *frontal notch* or *foramen*. The supraorbital margin ends laterally in the *zygomatic process*, which is strong and prominent, and articulates with the zygomatic bone. Running upwards and backwards from this process is a line which soon divides into the *superior and inferior temporal lines*.

The portion of the squama which projects downwards between the supra-orbital margins is known as the *nasal part*. It presents a rough, uneven interval, the *nasal notch*, which articulates on either side of the middle line with the nasal bone, and lateral to this with the frontal process of the maxilla and with the lacrimal. From the centre of the notch the *nasal process* projects downwards and forwards beneath the nasal bones and frontal processes of the maxillæ, and supports the bridge of the nose. The nasal process ends below in a sharp *frontal spine*, and on either side of this is a small grooved surface which forms part of the roof of the corresponding nasal cavity. The frontal spine forms part of the septum of the nose; it articulates in front with the crest of the nasal bones, behind with the lamina perpendicularis of the ethmoidal bone.

The *temporal surface*, below and behind the temporal lines, forms the anterior part of the temporal fossa, and gives origin to the Temporalis muscle.

The *cerebral surface* (fig 306) of the squama is concave. In the upper part of the middle line is a vertical groove, the *sagittal sulcus*, the edges of which unite below to form the *frontal crest*; the sulcus lodges the anterior part of the superior sagittal sinus, while its margins and the crest afford attachment to the anterior part of the *falx cerebri*. The crest ends below in a small notch which is converted into the *foramen cæcum* by articulation with the ethmoidal bone. The foramen cæcum varies in size in different skulls, and is frequently impervious; when open, it transmits a vein from the nose to the superior sagittal sinus. On either side of the middle line are depressions for the convolutions of the brain, and minute furrows for the anterior branches of

FIG. 306.—Frontal bone. Cerebral surface.

the middle meningeal vessels. Several small, irregular fossæ may be seen on either side of the sagittal sulcus, for the reception of the arachnoidal granulations.

The *border of the squama* is thick, strongly serrated, bevelled at the expense of the cerebral surface above, where it rests upon the parietal bones, and at the expense of the temporal surface on either side, where it receives the lateral pressure of those bones; it is continued below into a triangular, rough surface, which articulates with the great wing of the sphenoid.

Orbital part.—This part consists of two thin triangular *orbital plates*, which form the vaults of the orbits, and are separated from one another by a wide gap, the *ethmoidal notch*.

The *orbital surface* (fig. 306) of each orbital plate is smooth and concave, and presents, laterally, under cover of the zygomatic process, a shallow depression, the *lacrimal fossa*, for the lacrimal gland; below and behind the medial end of the supraorbital margin is a depression, the *fovea trochlearis*, or occasionally a small *spina trochlearis*, for the attachment of the fibrocartilaginous pulley

of the *Obliquus oculi superior*. The *cerebral surface* is convex, and marked by depressions corresponding to the convolutions of the frontal lobe of the brain, and faint grooves for the meningeal branches of the ethmoidal vessels.

The *ethmoidal notch* (*incisura ethmoidalis*) separates the two orbital plates; it is quadrilateral, and filled, in the articulated skull, by the *lamina cribrosa* of the ethmoidal bone. On the margins of the notch are several half-cells which, when united with corresponding half-cells on the upper surface of the ethmoidal bone, complete the ethmoidal air-cells. Two grooves cross each margin transversely; they are converted into the *anterior* and *posterior ethmoidal canals* by the ethmoidal bone, and open on the medial wall of the orbit. They transmit the anterior and posterior ethmoidal nerves and vessels. In front of the ethmoidal notch, and lateral to the frontal spine, are the openings of the *frontal air-sinuses*. These sinuses are two irregular cavities, which extend backwards, upwards, and lateralwards for a variable distance between the two tables of the bone; they are separated from one another by a thin bony septum, which is often deflected to one or other side of the middle line, with the result that the sinuses are seldom symmetrical. Rudimentary at birth, they are usually fairly well developed between the seventh and eighth years, but only reach their full development after puberty. They vary in size in different persons, and are larger in men than in women.* Each communicates with the middle meatus of the corresponding nasal cavity by means of a passage called the *frontonasal duct*.

The *posterior borders* of the *orbital plates* are thin and serrated, and articulate with the small wings of the sphenoidal bone; the lateral part of each usually appears in the middle fossa of the skull between the great and small wings of the sphenoidal bone.

Structure.—The squama and the zygomatic processes are thick and consist of spongy substance contained between two compact laminae; the spongy substance

is absent in the regions occupied by the frontal air-sinuses. The orbital part, composed entirely of compact bone, is thin and translucent, hence the facility with which the cranium can be penetrated through the roof of the orbit; when the frontal sinuses are exceptionally large they may extend backwards for a considerable distance into the orbital plates.

Ossification.—(fig. 307) The frontal bone is ossified in membrane from two *primary* centres which appear in the seventh or eighth week of foetal life, one above each supraorbital margin. From each of these centres ossification extends upwards to form

FIG. 307.—Frontal bone at birth.

the corresponding half of the squama, and backwards to form the orbital plate. The spine is ossified from a pair of *secondary* centres, one on either side of the middle line; similar centres appear in the nasal part and zygomatic processes. At birth the bone consists of two pieces separated by the frontal suture; union of the two pieces begins in the second year, and the frontal suture is usually obliterated, except at its lower part, by the eighth year.

* Logan Turner (*op. cit.*) gives the following measurements for a sinus of average size: height, 3.16 cm.; breadth, 2.58 cm.; depth from before backwards, 1.8 cm. Onodi (*op. cit.*) states that in infants of from one to twelve months the height of the frontal sinus varies from 3.5 mm. to 8 mm., and its width from 2 mm. to 6 mm., and that in the eighth year of life the height is from 14 mm. to 17 mm., and the width from 7 mm. to 9 mm.

THE ETHMOIDAL BONE (OS ETHMOIDALE)

The ethmoidal bone is cubical in shape, and exceedingly light; it is situated at the anterior part of the base of the cranium and assists in forming the medial walls of the orbital cavities and the roofs and lateral walls of the nasal cavities. It consists of four parts: a horizontal, perforated plate named the lamina cribrosa, a lamina perpendicularis, and two labyrinths or lateral masses.

The lamina cribrosa (fig. 308) occupies the ethmoidal notch of the frontal bone and helps to roof in the nasal cavities. Projecting upwards from the median line of this plate is a thick, smooth, triangular process, the *crista galli*, so called from its resemblance to a cock's comb. Its posterior border, long, thin, and curved, gives attachment to the falx cerebri. Its anterior border, short and thick, articulates with the frontal bone by two small projecting alar processes which complete the foramen cæcum. Its sides are smooth, and sometimes bulging from the presence of a small air-sinus in the interior. On either side of the crista galli, the lamina cribrosa is narrow and depressed; it supports the olfactory bulb and is perforated by foramina for the passage of the olfactory nerves. The foramina in its middle part are small and transmit the nerves to the roof of the nasal cavity; those in the medial and lateral parts are larger—the former transmit the nerves to the mucous membrane on the upper part

FIG. 308.—Ethmoidal bone, from above.

FIG. 309.—Lamina perpendicularis of ethmoidal bone. Shown by removing the right labyrinth.

of the nasal septum, the latter the nerves to the mucous membrane on the superior nasal concha. At the front part of the lamina cribrosa, on either side of the crista galli, is a small fissure which is occupied by a process of dura mater.

Lateral to this fissure is a foramen which transmits the anterior ethmoidal nerve to the nasal cavity; from this foramen a groove runs backwards to the anterior ethmoidal foramen.

The lamina perpendicularis (figs. 309, 310), thin, flattened and polygonal in form, descends from the under surface of the lamina cribrosa, and forms the upper part of the nasal septum; it is generally deflected a little to one or other side. The anterior border articulates with the spine of the frontal bone and the crest of the nasal bones. The posterior border articulates with the sphenoidal crest above and with the vomer below. The inferior border is thick, and serves for the attachment of the cartilage of the septum of the nose. The surfaces of the lamina are smooth, except above, where numerous grooves and canals are seen; these lead from the medial foramina on the lamina cribrosa and lodge filaments of the olfactory nerves.

FIG. 310.—Ethmoidal bone, from behind.

The labyrinth or lateral mass consists of a number of thin-walled ethmoidal air-cells, arranged in three groups, anterior, middle, and posterior, and interposed between two vertical plates of bone; the lateral plate forms part of the medial wall of the orbit, the medial plate, part of the corresponding nasal cavity.* In the disarticulated bone many of these ethmoidal air-cells are open, but in the articulated skull they are everywhere closed, except at their openings into the nasal cavity. The upper surface of the labyrinth (fig. 308) presents a number of cells, the walls of which are completed, in the articulated skull, by the edges of the ethmoidal notch of the frontal bone. Crossing this surface are two grooves which are converted into the anterior and posterior ethmoidal canals by articulation with the frontal bone. On the posterior surface (fig. 310) are large air-cells the walls of which are completed by the sphenoidal concha above and the orbital process

below. The lateral surface (fig. 311) consists of a thin, smooth, oblong plate, the lamina papyracea (os planum), which covers in the middle and posterior ethmoidal cells and forms a large part of the medial wall of the orbit; it articulates above with the orbital plate of the frontal bone,

FIG. 311.—Ethmoidal bone, from the right side.

of the palatine bone below. The lateral surface (fig. 311) consists of a thin, smooth, oblong plate, the lamina papyracea (os planum), which covers in the middle and posterior ethmoidal cells and forms a large part of the medial wall of the orbit; it articulates above with the orbital plate of the frontal bone,

* Some anatomists divide the ethmoidal air-cells into two groups, an anterior, comprising the cells which open into the middle meatus of the nose, and a posterior, those which open into the superior meatus.

below with the maxilla and the orbital process of the palatine bone, in front with the lacrimal, and behind with the sphenoidal bone (fig. 324).

In front of the lamina papyracea are some air-cells, the walls of which are completed by the lacrimal bone and the frontal process of the maxilla. A curved lamina, the *uncinate process*, projects downwards and backwards from this part of the labyrinth; it forms a small part of the medial wall of the maxillary sinus (fig. 324), and articulates with the ethmoidal process of the inferior nasal concha.

The *medial surface* of the labyrinth (fig. 312) forms part of the lateral wall of the corresponding nasal cavity; it consists of a thin lamella, which descends from the under surface of the lamina cribrosa, and ends in a free, convoluted

FIG. 312.—Lateral wall of nasal cavity, showing the ethmoidal bone (coloured red) and the inferior nasal concha (coloured blue) in position.

margin, the *middle nasal concha*. Its upper part is marked by numerous grooves, directed nearly vertically downwards from the lamina cribrosa; they lodge branches of the olfactory nerves, which are distributed to the mucous membrane covering the superior nasal concha. The posterior part of the medial surface is subdivided by a narrow, oblique fissure, the *superior meatus of the nose*, bounded above by a thin, curved plate, the *superior nasal concha*; the posterior ethmoidal cells open into this meatus. Below and in front of the superior meatus is the convex surface of the middle nasal concha; it extends along the whole length of the medial surface of the labyrinth. Its lower margin is free and thick, while its lateral surface is concave, and assists in forming the *middle meatus of the nose*. The middle ethmoidal cells produce a rounded swelling, named the *bullae ethmoidales*, on the lateral wall of the middle meatus; on this bulla, or immediately above it, the cells open into the meatus. A curved passage, termed the *infundibulum*, extends upwards and forwards from the middle meatus; it communicates with the anterior ethmoidal cells, and in rather more than 50 per cent. of skulls is continued upwards as the frontonasal duct into the frontal sinus.

Ossification.—The ethmoidal bone is ossified in the cartilaginous nasal capsule by three centres; one for the lamina perpendicularis, and one for each labyrinth.

The centre for each labyrinth appears in the region of the lamina papyracea between the fourth and fifth months of foetal life, and extends into the conchæ. At birth, the bone consists of the two labyrinths, which are small and ill-developed. During the first year after birth, the lamina perpendicularis and crista galli begin to ossify from a single centre, and are joined to the labyrinths about the beginning of the second year. The lamina cribrosa is ossified partly from the lamina perpendicularis and partly from the labyrinths. The ethmoidal cells begin to develop during foetal life, and in the new-born infant have the form of narrow pouches.

THE INFERIOR NASAL CONCHÆ (CONCHÆ NASALES INFERIORES)

The inferior nasal conchæ are curved lamina which extend horizontally along the lateral walls of the nasal cavities (fig. 312). Each bone has two surfaces, two borders, and two extremities.

The *medial surface* (fig. 313) is convex, perforated by numerous apertures, and traversed by longitudinal grooves for the lodgment of vessels. The *lateral surface* is concave (fig. 314), and forms part of the inferior meatus of the nasal cavity. The *upper border* is thin and irregular, and may be divided into three

FIG. 313.—Right inferior nasal concha.
Medial surface.

FIG. 314.—Right inferior nasal concha.
Lateral surface.

portions: of these, the anterior articulates with the crista conchalis of the maxilla, and the posterior with the crista conchalis of the palatine bone. The middle portion presents three processes, which vary much in their size and form. Of these, the *lacrimal process* is small and pointed and is situated at the junction of the anterior fourth with the posterior three-fourths of the bone: it articulates, by its apex, with the descending process of the lacrimal bone, and, by its margins, with the edges of the nasolacrimal groove on the medial surface of the body of the maxilla, and thus assists in forming the canal for the nasolacrimal duct. Behind this process a thin plate, the *ethmoidal process*, ascends to join the uncinate process of the ethmoid; from the middle part of the superior border a thin lamina, the *maxillary process*, curves downwards and lateralwards; it articulates with the maxilla and the maxillary process of the palatine bone, and forms a part of the medial wall of the maxillary sinus (fig. 324). The *inferior border* is free, thick, and spongy in structure, more especially in the middle of the bone. Both *extremities* are more or less pointed, the posterior being the more tapered.

Ossification.—The inferior nasal concha is ossified from a single centre; this appears about the fifth month of foetal life in the maxilloturbinal cartilage which is the incurved lower border of the lateral wall of the nasal capsule. It is detached from the remainder of the nasal capsule during ossification.

THE LACRIMAL BONES (OSSA LACRIMALIA)

The lacrimal bones, the smallest and most fragile of the cranial bones, are situated at the front parts of the medial walls of the orbits (fig. 316). Each bone has two surfaces and four borders. The *lateral or orbital surface* (fig. 315) is divided by a vertical ridge, the *posterior lacrimal crest*, into two parts. In

front of this crest is the *lacrimal groove*, the inner margin of which unites with the *frontal process of the maxilla* to complete the *lacrimal fossa*. The upper part of this fossa lodges the *lacrimal sac*; the lower, part of the *nasolacrimal duct*. The portion behind the crest is smooth, and forms part of the medial wall of the orbit. The crest, with a part of the orbital surface immediately behind it, gives origin to the *lacrimal part of the Orbicularis oculi*, and ends below in a small, hook-like projection, the *lacrimal hamulus*, which articulates with the *lacrimal tubercle of the maxilla* and completes the upper orifice of the *lacrimal canal*; the *lacrimal hamulus* sometimes exists as a separate piece, and is then called the *lesser lacrimal bone*. On the *medial or nasal surface* is a vertical furrow, corresponding to the posterior *lacrimal crest* on the lateral surface. The area in front of this furrow forms part of the *middle meatus of the nose*; that behind it articulates with the *ethmoidal bone*, and completes some of the anterior *ethmoidal air-cells*. Of the *four borders* the *anterior* articulates with the *frontal process of the maxilla*; the *posterior* with the *lamina papyracea of the ethmoidal bone*; the *superior* with the *frontal bone*. The *inferior* is divided by the lower edge of the posterior *lacrimal crest* into two parts: the *posterior part* articulates with the *orbital plate of the maxilla*; the *anterior* is prolonged downwards as the *descending process*, which articulates with the *lacrimal process of the inferior nasal concha* and with the edges of the *nasolacrimal groove on the maxilla*, and assists in forming the canal for the *nasolacrimal duct*.

FIG. 315.—Left lacrimal bone. Orbital surface. (Enlarged.)

FIG. 316.—Articulation of nasal and lacrimal bones with maxilla.

Ossification.—The lacrimal is ossified from a single centre, which appears about the twelfth week of foetal life in the membrane covering the cartilaginous nasal capsule.

THE NASAL BONES (OSSA NASALIA)

The **nasal bones** are two small oblong bones, varying in size and form in different individuals; they are placed side by side between the frontal processes of the maxillæ, and form, by their junction, 'the bridge' of the nose (fig. 316).

Each has two surfaces and four borders. The *outer surface* (fig. 317) is concavo-convex from above downwards, convex from side to side; it is covered by the *Procerus* and *Compressor naris*, and is perforated near its centre by a foramen, for the transmission of a small vein. The *inner surface* (fig. 318) is concave from side to side, and is traversed from above downwards by a groove, the *ethmoidal sulcus*, for the passage of the *anterior ethmoidal nerve*. The *superior border*, thick and serrated, articulates with the nasal notch of the frontal bone. The *inferior border* is thin and notched, and gives attachment to the lateral cartilage of the nose. The *lateral border* articulates with the frontal process of the maxilla. The *medial border*, thicker above than below, articulates with its fellow of the opposite side, and is prolonged behind into a vertical crest which forms part of the septum of the nose: this crest articulates, from above downwards, with the *frontal spine*, the *lamina perpendicularis* of the ethmoidal bone, and the cartilage of the septum of the nose.

FIG. 317.—Right nasal bone.
Outer surface.

FIG. 318.—Right nasal bone.
Inner surface.

Ossification.—Each bone is ossified from one centre, which appears at the beginning of the third month of foetal life in the membrane overlying the front part of the cartilaginous nasal capsule.

THE VOMER

The *vomer* is thin, somewhat quadrilateral in shape, and forms the hinder and lower part of the nasal septum (fig. 319); it has two surfaces and four borders. The *surfaces* (fig. 320) are marked by small furrows for blood-vessels, and on each is the *nasopalatine groove* which runs obliquely downwards and forwards, and lodges the *nasopalatine nerve* and vessels. The *superior border*, the thickest, presents a deep furrow, bounded on either side by a horizontal projecting ala; the furrow receives the rostrum of the sphenoidal bone, and the alae articulate with the sphenoidal conchæ, the sphenoidal processes of the palatine bones and the vaginal processes of the medial pterygoid laminae of the sphenoidal bone. The *inferior border* articulates with the nasal crest formed by the maxillæ and palatine bones. The *anterior border* is the longest; its upper half articulates with the *lamina perpendicularis* of the ethmoidal bone, its lower is grooved for the reception of the inferior margin of the cartilage of the septum of the nose. The *posterior border* is free, concave, and separates the choanæ or posterior nasal apertures; it is thick and bifid above, thin below. The anterior end of the vomer articulates with the posterior margin of the incisor crest of the maxillæ and projects downwards between the incisive canals.

Ossification.—At an early period the septum of the nose consists of a plate of cartilage. The superior part of this cartilage is ossified to form the *lamina perpendicularis* of the ethmoid; its antero-inferior portion persists as the cartilage of the septum, whilst the vomer is ossified in the membrane covering its postero-inferior part. About the eighth week of foetal life two ossific centres, one on either side of the middle line, appear in this part of the membrane, medial to and a little behind the paraseptal cartilages. About the third month these centres unite below,

and thus a deep groove is formed (fig. 321) in which the cartilage of the septum is lodged. As growth proceeds, the union of the bony lamellæ extends upwards and forwards, and at the same time the intervening plate of cartilage undergoes

FIG. 319.—Median wall of left nasal cavity, showing vomer *in situ*.

absorption. By the age of puberty the lamellæ are almost completely united, but evidence of the bilaminar origin of the bone is seen in the everted alæ of its upper border and the groove on its anterior border. Up to a certain stage the vomer is entirely derived from membrane, but 'it becomes added to by the ossification of the hinder end of the anterior paraseptal cartilage.* From this part of the

FIG. 320.—The vomer.

FIG. 321.—Vomer of infant.

ossified anterior paraseptal cartilage a plate of bone descends by the side of the primary part of the vomer, and fuses with it. The vomeronasal cartilage of Jacobson is the persistent anterior paraseptal cartilage.*

* Fawcett, *Journal of Anatomy and Physiology*, vol. xlv.

SUTURAL BONES (OSSA SUTURARUM)

In addition to the usual centres of ossification of the cranial bones, others may occur in the course of the sutures, giving rise to irregular, isolated, *sutural* or *Wormian** bones. They occur most frequently in the course of the lambdoidal suture, but are occasionally seen at the fonticuli, especially the posterior. One, the *pterion ossicle*, sometimes exists between the sphenoidal angle of the parietal and the great wing of the sphenoid. They have a tendency to be more or less symmetrical on the two sides of the skull, and vary much in size. Their number is generally limited to two or three; but more than a hundred have been found in the skull of a hydrocephalic subject.

Applied Anatomy.—An arrest in the ossifying process may give rise to deficiencies, gaps, or fissures in the cranium, which are of importance from a medico-legal point of view, as they are liable to be mistaken for fractures. The fissures generally extend from the margins towards the centre of a bone, but the gaps may be found in the middle as well as at the edges. In course of time they may become filled with thin laminae of bone. In many of these cases, however, the gaps must be regarded as due to absorption of bone already formed rather than as congenital deficiencies; this is especially the case when they appear in the centre of a bone such as the parietal, the ossification of which has already been described as occurring in a regular manner radiating from two centres. The condition is most commonly seen in very badly nourished children affected with congenital syphilis, and is called *craniotabes*.

FACIAL BONES (OSSA FACIEI)

THE MAXILLÆ

The maxillæ are the largest bones of the face, excepting the mandible, and form, by their union, the whole of the upper jaw. Each assists in completing the roof of the mouth, the floor and lateral wall of the nose, and the floor of the orbit; they also enter into the formation of the infratemporal and pterygo-palatine fossæ, and the inferior orbital and pterygomaxillary fissures.

Each bone consists of a body and four processes—zygomatic, frontal, alveolar, and palatine.

The body is somewhat pyramidal in shape. It has four surfaces,—anterior, infratemporal, orbit. and nasal—and these enclose a large cavity, the maxillary sinus or antrum of Highmore.

The *anterior surface* (fig. 322) is directed forwards and lateralwards. On its lower part is a series of eminences (*juga alveolaria*) corresponding to the positions of the roots of the teeth. Just above those of the incisor teeth is a depression, the *incisive fossa*, which gives origin to the *Depressor septi*; to the alveolar border below the fossa a slip of the *Orbicularis oris* is attached; above and a little lateral to it, the *Nasalis* arises. Lateral to the incisive fossa is a larger and deeper depression, the *canine fossa*; it is separated from the incisive fossa by the *canine eminence*, which corresponds to the socket of the canine tooth; the fossa gives origin to the *Caninus*. Above the canine fossa is the *infraorbital foramen*, the end of the infraorbital canal; it transmits the infraorbital vessels and nerve. Above the foramen is the margin of the orbit, which gives origin to the orbital head of the *Quadratus labii superioris*. Medially, the anterior surface is limited by a deep concavity, the *nasal notch*; the margin of the notch gives attachment to the *Dilatator naris posterior* and ends below in a pointed process, which with its fellow of the opposite side forms the *anterior nasal spine*.

The *infratemporal surface* (fig. 322) is convex, directed backwards and lateralwards, and forms part of the infratemporal fossa. It is separated from the anterior surface by the zygomatic process and by a ridge which extends upwards from the socket of the first molar tooth. It is pierced near its centre by the apertures of two or three *alveolar canals*, which transmit the posterior superior alveolar vessels and nerves. At the lower part of this surface is a rounded eminence, the *maxillary tuberosity*, which is rough for articulation with the pyramidal process of the palatine bone; it gives origin to a few

* Old Worm, Professor of Anatomy at Copenhagen 1624-1639, was erroneously supposed to have given the first detailed description of these bones.

fibres of the *Pterygoideus internus*, and in some cases articulates with the lateral pterygoid lamina of the sphenoidal bone. Immediately above this is a smooth surface, which forms the anterior boundary of the pterygopalatine fossa, and is grooved for the maxillary nerve; this groove is directed lateralwards and slightly upwards, and is continuous with the infraorbital groove on the orbital surface.

The *orbital surface* (fig. 322) is smooth and triangular, and forms the greater part of the floor of the orbit. Its *medial border* presents anteriorly a notch, the *lacrimal notch*, behind which it articulates from before backwards with the lacrimal bone, the lamina papyracea of the ethmoidal bone, and the orbital process of the palatine bone. Its *posterior border* is smooth and rounded; it forms the anterior margin of the inferior orbital fissure, and its central part

FIG. 322.—Left maxilla. Outer surface.

is notched by the commencement of the infraorbital groove. The *anterior border* forms a small part of the circumference of the base of the orbit, and is continuous medially with the frontal process, and laterally with the zygomatic process. The *infraorbital groove*, for the passage of the infraorbital vessels and nerve, begins at the middle of the posterior border, where it is continuous with the groove near the upper edge of the infratemporal surface; it passes forwards and ends in the *infraorbital canal*, which opens just below the margin of the orbit. At the medial and front part of the orbital surface, just lateral to the lacrimal groove, is a depression, which gives origin to the *Obliquus oculi inferior*.

The *nasal surface* (fig. 323) presents in its upper and posterior part a large, irregular opening leading into the maxillary sinus. At the upper border of this aperture are some broken air-cells, which, in the articulated skull, are closed by the ethmoidal and lacrimal bones. Below it is a smooth concavity which forms part of the inferior meatus of the nasal cavity, and behind it is a rough surface for articulation with the vertical part of the palatine bone; this surface is traversed by a groove, which begins near the middle of the posterior border, runs obliquely downwards and forwards, and is converted into the *pterygo-palatine canal* by the vertical part of the palatine bone and the pterygoid process of the sphenoidal bone. In front of the opening of the maxillary sinus is a deep groove, the *sulcus lacrimalis*, which is converted into the *nasolacrimal canal* by the lacrimal bone and inferior nasal concha; this canal opens into the inferior meatus of the nose and transmits the *nasolacrimal duct*. More

anteriorly is an oblique ridge, the *crista conchalis*, for articulation with the inferior nasal concha. The shallow concavity below this ridge forms part of the inferior meatus of the nose, and that above it part of the atrium of the middle meatus.

The **maxillary sinus** or **antrum of Highmore** is a large pyramidal cavity within the body of the maxilla: its *apex*, directed laterally, is formed by the zygomatic process; its *base*, directed medially, by the lateral wall of the nose. Its walls are thin, and correspond to the nasal, orbital, anterior, and infratemporal surfaces of the body of the bone. Its base, or nasal wall, presents, in the disarticulated bone, a large, irregular aperture communicating with the nasal cavity. In the articulated skull this aperture is much reduced in size by the following bones: the uncinat process of the ethmoidal above, the

FIG. 323.—Left maxilla. Nasal surface.

maxillary process of the inferior nasal concha below, the vertical part of the palatine behind, and a small part of the lacrimal above and in front (fig. 324). The sinus communicates with the middle meatus of the nose, generally by two small apertures, one of which is usually closed, in the recent state, by mucous membrane. On the *posterior wall* are the *alveolar canals*, transmitting the posterior superior alveolar vessels and nerves to the molar teeth. The *floor* is formed by the alveolar process of the maxilla, and its lowest part is usually about 1.25 cm. below the level of the floor of the nasal cavity. In a large proportion of cases radiating septa of varying sizes spring from the floor of the sinus in the intervals between adjacent teeth; in some cases the floor is perforated by the fangs of the molar teeth.* The infraorbital canal usually projects into the sinus as a well-marked ridge extending from the roof to the anterior wall; ridges, caused by the alveolar canals, are sometimes seen in the posterior wall. The size of the cavity varies in different skulls, and even on the two sides of the same skull.†

* The number of teeth whose roots are in relation with the floor of the antrum is variable. The sinus may extend so as to be in relation to all the teeth of the true maxilla, from the canine to the third molar.—(Salter.)

† Logan Turner (*op. cit.*) gives the following measurements as those of an average-sized sinus: vertical height opposite first molar tooth, 3.5 cm.; transverse breadth, 2.5 cm.; and anteroposterior depth, 3.2 cm.

Applied Anatomy.—The extreme thinness of the walls of this cavity affords an explanation of the fact that a tumour growing from the maxillary sinus and encroaching upon the adjacent parts may push up the floor of the orbit, and displace the eyeball; may project into the nose; may protrude forwards on to the cheek; or may make its way backwards into the infratemporal fossa, or downwards into the mouth.

The **zygomatic process** is a rough triangular eminence, situated at the angle of separation of the anterior, infratemporal, and orbital surfaces. *In front* it forms part of the anterior surface of the body of the bone; *behind*, it is concave, and continuous with the infratemporal surface; *above*, it is rough and serrated for articulation with the zygomatic bone; *below*, it presents the prominent arched border which marks the division between the anterior and infratemporal surfaces.

FIG. 324.—Left maxillary sinus opened from the exterior.

The **frontal process** projects upwards and backwards between the nasal and lacrimal bones. Its *lateral surface* is smooth, continuous below with the anterior surface of the body, and gives attachment to the angular head of the *Quadratus labii superioris*, the *Orbicularis oculi*, and the *medial palpebral ligament*. Its *medial surface* forms part of the lateral wall of the nasal cavity; a rough, uneven area, at its upper part, articulates with the ethmoidal bone and closes in the anterior ethmoidal cells; below this is an oblique ridge, the *crista ethmoidalis*, the posterior end of which articulates with the middle nasal concha, while the anterior part is termed the *agger nasi*; the *crista ethmoidalis* forms the upper limit of the atrium of the middle meatus. The *upper extremity* articulates with the frontal bone, and the *anterior border* with the nasal bone; the *posterior border* is thick, and hollowed into a groove, which is continuous below with the sulcus lacimalis on the nasal surface of the body and posteriorly, in the articulated skull, with the lacrimal groove on the lacrimal bone, the two grooves forming the *lacrimal fossa* for the lodgment of the lacrimal sac. The lateral margin of the groove is named the *anterior lacrimal crest*, and is continuous below with the orbital margin; at its junction with the orbital surface

is a small tubercle, the *lacrimal tubercle*, which serves, in the living subject, as a guide to the position of the lacrimal sac.

The **alveolar process**, thick and arched, is broader behind than in front, and excavated into cavities or alveoli for the reception of the roots of the teeth. These cavities are eight in number, and vary in size and depth according to the teeth they contain. That for the canine tooth is the deepest; those for the molars are the widest, and are subdivided into three minor cavities by septa; those for the incisors are single, but deep and narrow. The *Buccinator* arises from the outer surface of this process, as far forward as the first molar tooth. When the maxillæ are articulated with each other, their alveolar processes together form the *alveolar arch*.

FIG. 325.—The bony palate and alveolar arch.

The **palatine process**, thick and strong, is horizontal and projects medially from the nasal surface of the bone. It forms a considerable part of the floor of the nose and the roof of the mouth, and is much thicker in front than behind. Its *inferior surface* (fig. 325), concave, rough and uneven, forms, with the palatine process of the opposite bone, the anterior three-fourths of the hard palate. It is perforated by numerous foramina for the passage of the nutrient vessels, and presents depressions for the lodgment of the palatine glands; it is channelled at the posterior part of its lateral border by two grooves, for the transmission of the descending palatine vessels, and the anterior palatine nerve. When the two maxillæ are articulated, a funnel-shaped opening, the *incisive foramen*, is seen in the middle line, immediately behind the incisor teeth. In this opening the orifices of two lateral canals are visible; they are named the *incisive canals* or *foramina of Stensen*; each leads upwards into the corresponding nasal cavity and transmits the terminal branch of the greater palatine artery and the nasopalatine nerve. Occasionally there are two additional apertures in the middle line; they are termed the *foramina of Scarpa*, and when present transmit the nasopalatine nerves, the left passing through the anterior, and the right through the posterior foramen. On the under surface

of the palatine process, a delicate suture, well seen in young skulls, may sometimes be noticed extending lateralwards and forwards from the incisive foramen to the interval between the lateral incisor and the canine teeth. The small part in front of this suture constitutes the *premaxilla*, or *os incisivum*, which in most vertebrates forms an independent bone; it includes the whole thickness of the alveolus, the corresponding part of the floor of the nose and the anterior nasal spine, and contains the sockets of the incisor teeth. The *upper surface* of the palatine process is concave from side to side, smooth, and forms the greater part of the floor of the nasal cavity; close to its medial margin is the upper orifice of the incisive canal. The *lateral border* of the process is fused with the rest of the bone. The *medial border*, thicker in front than behind, is

FIG. 326.—Anterior surface of maxilla at birth.

FIG. 327.—Inferior surface of maxilla at birth.

FIG. 328.—Nasal surface of maxilla at birth.

raised into a ridge, the *nasal crest*, which, with the corresponding ridge of the opposite bone, forms a groove for the reception of the vomer. The front part of this ridge rises to a considerable height, and is named the *incisor crest*; it is prolonged forwards into a sharp process, which, together with the similar process of the opposite bone, forms the *anterior nasal spine*. The *posterior border* is serrated for articulation with the horizontal part of the palatine bone.

Ossification.—The maxilla is mainly developed in membrane. Mall* and Fawcett† have shown that it is ossified from two centres, one for the maxilla proper and one for the premaxilla. These centres appear at the end of the sixth week of foetal life, that for the maxilla proper commencing above the canine tooth-germ; they unite at the end of the second or early in the third month, but the suture between them (fig. 327) persists on the palate until nearly middle life; the frontal process of the bone is developed from both centres. The ossifying maxilla invades and incorporates the paranasal process of the cartilaginous nasal capsule, and this may account for the small islands of cartilage which are sometimes found in the ossifying maxilla. The maxillary sinus appears as a shallow groove (fig. 328) on the nasal surface of the bone about the fourth month of foetal life, but does not reach its full size until after the second dentition. The infraorbital vessels and nerve

* *American Journal of Anatomy*, vol. v. 1906.

† *Journal of Anatomy and Physiology*, vol. xlv. 1911.

lie for a time in an open groove, the anterior part of which is converted into the infraorbital canal by a lamina of bone which grows from the lateral side of the groove.

CHANGES PRODUCED IN THE MAXILLA BY AGE.

At birth the transverse and anteroposterior diameters of the bone are each greater than the vertical. The frontal process is well-marked and the body of the bone consists of little more than the alveolar process, the tooth-sockets reaching almost to the floor of the orbit. The maxillary sinus appears as a furrow on the lateral wall of the nose. In the adult the vertical diameter is the greatest, owing to the development of the alveolar process and the increase in size of the sinus. In old age, the bone reverts in some measure to the infantile condition: its height is diminished, and after the loss of the teeth the alveolar process is absorbed, and the lower part of the bone contracted and reduced in thickness.

THE PALATINE BONES (OSSA PALATINA)

The palatine bones are situated at the posterior part of the nasal cavity between the maxillæ and the pterygoid processes of the sphenoidal bone (fig. 329). Each assists in forming the floor and lateral wall of the nasal cavity, the roof of the mouth, and the floor of the orbit; it enters into the formation of the

FIG. 329.—Articulation of left palatine bone and left maxilla.

pterygopalatine and pterygoid fossæ, and the inferior orbital fissure. It somewhat resembles the letter L, and consists of a horizontal and a vertical part, and three outstanding processes—viz. the pyramidal process, which is directed backwards, lateralwards, and downwards, from the junction of the two parts, and the orbital and sphenoidal processes, which surmount the vertical part, and are separated by a deep notch, the sphenopalatine notch.

The horizontal part (figs. 330, 331) is quadrilateral, and has two surfaces and four borders. The *nasal surface*, concave from side to side, forms the posterior part of the floor of the nasal cavity. The *palatine surface* forms, with the corresponding surface of the opposite bone, the posterior fourth of the hard palate; near its posterior margin is a curved ridge. The *posterior border* is thin and concave; to it and to the palatine surface as far forwards as the curved ridge just described the expanded tendon of the Tensor veli palatini is attached. Its medial end is thin and pointed, and, when united with that of the opposite bone, forms a projecting process, the *posterior nasal*

spine, for the attachment of the Musculus uvula. The anterior border is serrated, and articulates with the palatine process of the maxilla. The lateral border is united with the lower margin of the vertical part, and is grooved by the lower

FIG. 330.—Left palatine bone. Nasal aspect. (Enlarged.)

end of the pterygopalatine canal. The medial border, thick and serrated, articulates with the corresponding border of the opposite bone, and forms with it a crest which articulates with the posterior part of the lower edge of the vomer, and is continuous anteriorly with the nasal crest of the maxillæ.

The vertical part (figs. 330, 331), thin and of an oblong form, has two surfaces and four borders.

The nasal surface exhibits at its lower part a broad, shallow depression which forms part of the inferior meatus of the nasal cavity. Immediately above this is a horizontal ridge, the crista conchalis, for articulation with the inferior nasal concha; still higher is a second broad, shallow depression, which forms part of the middle meatus, and is limited above by the crista ethmoidalis, for articulation with the middle nasal concha. Above the crista ethmoidalis is a narrow, horizontal groove, which forms part of the superior meatus.

The maxillary surface is rough and irregular throughout the greater part of its extent, for articulation with the nasal surface of the maxilla; its upper and posterior part is smooth and forms the medial wall of the pterygopalatine fossa; its front portion is also smooth and forms the posterior part of the medial wall of the maxillary sinus.

On the posterior part of the maxillary surface is a deep vertical groove, the pterygopalatine sulcus, which in the articulated skull is converted into the pterygopalatine canal by the maxilla and the pterygoid process of the sphenoidal bone; this canal transmits the descending palatine vessels, and the palatine nerves.

FIG. 331.—Left palatine bone. Posterior aspect. (Enlarged.)

The *anterior border* is thin and irregular ; at the level of the *crista conchalis* is a pointed, projecting lamina, the *maxillary process*, which is directed forwards below and behind the maxillary process of the inferior nasal concha with which it articulates, and assists in forming the medial wall of the maxillary sinus. The *posterior border* (fig. 331) presents a deep groove, the edges of which are serrated for articulation with the medial pterygoid lamina of the sphenoidal bone. This border is continuous above with the sphenoidal process ; below, it expands into the pyramidal process. The *superior border* supports the orbital process in front and the sphenoidal process behind. These processes are separated by the *sphenopalatine notch*, which is converted into the *sphenopalatine foramen* by the under surface of the body of the sphenoidal bone. In the articulated skull this foramen leads from the pterygopalatine fossa into the posterior part of the superior meatus of the nose, and transmits the sphenopalatine vessels and the posterior superior nasal nerves. The *inferior border* is fused with the lateral edge of the horizontal part, and in front of the pyramidal process is grooved by the lower end of the pterygopalatine canal.

The *pyramidal process* (tuberosity) projects backwards, lateralwards, and downwards from the junction of the horizontal and vertical parts of the bone, and fits into the angular interval between the lower ends of the pterygoid laminae. On its *posterior surface* is a smooth, grooved, triangular area, limited on either side by a rough articular furrow. The furrows articulate with the pterygoid laminae, while the grooved triangular area completes the lower part of the pterygoid fossa and gives origin to a few fibres of the *Pterygoideus internus*. The anterior part of the *lateral surface* is rough for articulation with the maxillary tuberosity ; its posterior part consists of a smooth triangular area which appears, in the articulated skull, at the lower part of the infratemporal fossa between the maxillary tuberosity and the lateral pterygoid lamina. In the *base* of the pyramidal process, close to its union with the horizontal part, are the lesser palatine foramina for the transmission of the middle and posterior palatine nerves.

The *orbital process* is directed upwards and lateralwards from the front of the vertical part, to which it is joined by a constricted neck. It encloses an air-cell, and presents *five surfaces*, of which three are articular and two non-articular. The articular surfaces are : (1) the *anterior* or *maxillary*, of an oblong form, is directed forwards, lateralwards, and downwards, and articulates with the maxilla ; (2) the *posterior* or *sphenoidal*, directed backwards, upwards, and medialwards, presents the opening of the air-cell, which usually communicates with the sphenoidal sinus ; the margins of the opening articulate with the sphenoidal concha ; (3) the *medial* or *ethmoidal*, directed medialwards and forwards, articulates with the labyrinth of the ethmoidal bone. In some cases, the air-cell opens on this surface and then communicates with the posterior ethmoidal cells ; more rarely it opens on the ethmoidal and sphenoidal surfaces, and then communicates with the posterior ethmoidal cells and the sphenoidal sinus. The non-articular surfaces are : (1) the *superior* or *orbital*, triangular in shape, is directed upwards and lateralwards, and forms the posterior part of the floor of the orbit ; and (2) the *lateral*, of an oblong form, is directed towards the pterygopalatine fossa, and is separated from the orbital surface by a rounded border, which enters into the formation of the medial part of the inferior orbital fissure ; on this surface is a *transverse groove* which lodges the maxillary nerve and is continuous with the groove on the upper part of the infratemporal surface of the maxilla.

The *sphenoidal process* is a thin, compressed plate, smaller and on a lower level than the orbital process ; it is directed upwards and medialwards. Its *superior surface* articulates with the under surface of the sphenoidal concha and the root of the medial pterygoid lamina ; it presents a *groove* which contributes to the formation of the pharyngeal canal. The *inferomedial surface* is concave, and forms a small part of the roof and lateral wall of the nasal cavity. The posterior part of the *lateral surface* articulates with the medial pterygoid lamina ; the anterior part is smooth, and forms a portion of the medial wall of the pterygopalatine fossa. The *posterior border* is rough and articulates with the vaginal process of the medial pterygoid lamina. The *anterior border* forms the posterior boundary of the sphenopalatine notch. The *medial border* articulates with the ala of the vomer.

The orbital and sphenoidal processes are separated from one another by the *sphenopalatine notch* which is converted into the sphenopalatine foramen by the under surface of the body of the sphenoidal bone ; sometimes the two processes are united by a spicule of bone which then completes the upper boundary of the foramen.

Ossification.—The palatine bone is ossified in membrane from a single centre, which makes its appearance in the eighth week of foetal life in the vertical part at the side of the nasal cavity. From this point ossification spreads upwards into the orbital and sphenoidal processes, medialwards into the horizontal part, and downwards into the pyramidal process.

At the time of birth the height of the vertical part is about equal to the transverse width of the horizontal part, whereas in the adult it measures nearly twice as much.

THE ZYGOMATIC BONES (OSSA ZYGOMATICA)

The **zygomatic** or **malar** bones are situated at the upper and lateral parts of the face. Each forms the prominence of the cheek, part of the lateral wall and floor of the orbit, and parts of the temporal and infratemporal fossæ

FIG. 332.—Left zygomatic bone *in situ*.

(fig. 332) ; it is quadrangular in shape and has two surfaces, four borders, and four processes.

The *malar surface* (figs. 332, 333) is convex and is perforated near its orbital border by the *zygomaticofacial foramen* for the passage of the *zygomaticofacial nerve and vessels* ; below this foramen is a slight elevation, which gives origin to the *Zygomaticus*. The *temporal surface* (fig. 334), directed downwards and medialwards, is concave, presenting anteriorly a rough, triangular area, for articulation with the maxilla, and posteriorly a smooth, concave surface, the upper part of which forms the anterior boundary of the temporal fossa, the lower, a part of the infratemporal fossa. Near the middle of this surface is the *zygomaticotemporal foramen* for the transmission of the *zygomaticotemporal nerve*.

The *anterosuperior* or *orbital border* is smooth, concave, and forms a considerable part of the circumference of the base of the orbit. The *anteroinferior* or *maxillary border* is rough, and articulates with the maxilla ; near the orbital margin it gives origin to the zygomatic head of the *Quadratus labii superioris*. The *posterosuperior* or *temporal border*, curved like an italic letter *f*, is continuous above with the commencement of the temporal line, and below with

the upper border of the zygomatic arch; the temporal fascia is attached to it. The posteroinferior or zygomatic border affords attachment by its rough edge to the Masseter.

The frontosphenoidal process is thick and serrated, and articulates with the zygomatic process of the frontal bone. On its orbital surface, just within the orbital margin and about 11 mm. below the zygomaticofrontal suture is a tubercle of varying size and form, but present in 95 per cent. of skulls (Whitnall *). The orbital process is a thick, strong plate, projecting backwards and medialwards from the orbital margin. Its orbital surface forms, by its junction with the orbital surface of the maxilla and with the great wing of the sphenoidal bone, part of the floor and lateral wall of the orbit. On it are usually seen the orifices of two canals, the zygomatico-orbital foramina; one of these canals opens into the temporal fossa, the other on the malar surface of the bone; the former transmits the zygomaticotemporal, the latter the zygomaticofacial nerve. Its temporal surface, smooth and convex, forms parts of

FIG. 333.—Left zygomatic bone.
Malar surface.

FIG. 334.—Left zygomatic bone.
Temporal surface.

the temporal and infratemporal fossæ. Its anterior margin, smooth and rounded, is part of the circumference of the base of the orbit. Its superior margin, rough, and directed horizontally, articulates with the frontal bone behind the zygomatic process. Its posterior margin is serrated for articulation with the great wing of the sphenoidal bone and the orbital surface of the maxilla. At the angle of junction of the sphenoidal and maxillary portions, a short, concave, non-articular part is generally seen; this forms the anterior boundary of the inferior orbital fissure; this non-articular part is sometimes absent, and the fissure is then completed by the junction of the maxilla and the sphenoidal bone, or by the interposition of a small sutural bone in the angular interval between them. The infraorbital process is pointed and articulates with the maxilla, just above the infraorbital foramen. The temporal process is directed backwards and ends in an oblique serrated margin which articulates with the zygomatic process of the temporal.

Ossification.—The zygomatic bone is ossified from one centre which appears about the eighth week of foetal life below the zygomatic (temporomalar) nerve. The bone is sometimes divided by a horizontal suture into an upper larger, and a lower smaller division. In some quadrumana the zygomatic bone consists of two parts, an orbital and a malar.

* *Journal of Anatomy and Physiology*, vol. xiv.—The structures attached to this tubercle are: (1) the check ligament of the Rectus lateralis; (2) the lateral end of the aponeurosis of the Levator palpebræ superioris; (3) the suspensory ligament of the eye (Lockwood); and (4) the lateral extremities of the superior and inferior tarsi.

THE MANDIBLE (MANDIBULA)

The **mandible**, the largest and strongest bone of the face, consists of a curved, horizontal portion, the *body*, from the ends of which two perpendicular portions, the *rami*, project upwards.

The *body* is curved somewhat like a horseshoe, and has two surfaces and two borders. The *external surface* (fig. 335) is marked in the upper part of the median line by a faint ridge, indicating the *symphysis* or junction of the two pieces of which the bone is composed at an early period of life. This ridge divides below and encloses a triangular eminence, the *mental protuberance*, the base of which is depressed in the centre but raised on either side to form the *mental tubercle*. On either side of the ridge, just below the incisor teeth, is the *incisive fossa*, which gives origin to the *Mentalis* and to a small portion of the *Orbicularis oris*. Below the second premolar tooth, on either side, midway

FIG. 335.—Mandible. External surface. Side view.

between the upper and lower borders of the body, is the *mental foramen*, for the exit of the mental vessels and nerve. Running backwards and upwards from each mental tubercle is a faint ridge, the *oblique line*, which is continuous with the anterior border of the ramus; it affords attachment to the *Quadratus labii inferioris* and *Triangularis*; the *Platysma* is attached below it.

The *internal surface* (fig. 336) is concave from side to side. Near the lower part of the symphysis is a pair of laterally placed spines, termed the *mental spines*, which give origin to the *Genioglossi*. Immediately below these is a second pair of spines, or more frequently a median ridge or impression for the origins of the *Geniohyoidei*. In some cases the mental spines are fused to form a single eminence; in others they are absent, and their position is indicated merely by an irregularity of the surface. Above the mental spines a median foramen and furrow are sometimes present; they mark the line of union of the halves of the bone. Below the mental spines, on either side of the middle line, is an oval depression, the *digastric fossa*, for the attachment of the anterior belly of the *Digastricus*. Extending upwards and backwards on either side from the lower part of the symphysis to a point behind the last molar tooth is the *mylohyoid line* which gives origin to the *Mylohyoideus*; the posterior part of this line, near the alveolar margin, gives attachment to a small part of the *Constrictor pharyngis superior*, and to the *pterygomandibular raphe*. Above the anterior part of this line is a smooth triangular area against which the *sublingual gland* rests, and below the posterior part, an oval fossa for the *submaxillary gland*.

The *alveolar part* or upper portion of the body is hollowed into sixteen cavities or alveoli, for the reception of the teeth; these cavities vary in depth and size, and are single or subdivided by septa, according to the teeth which they contain. From the lateral surface of the alveolar part, on either side, the Buccinator takes origin as far forwards as the first molar tooth. The *inferior border* or *base* of the mandible is rounded, and is thicker in front than behind: at the point where it joins the lower border of the ramus a shallow groove, for the external maxillary artery, may be present.

The *ramus* is quadrilateral in shape, and has two surfaces, four borders, and two processes. The *lateral surface* (fig. 335) is flat and marked by oblique ridges at its lower part; it gives attachment throughout nearly the whole of its extent to the Masseter. The *medial surface* (fig. 336) presents about its centre the *mandibular foramen*, which transmits the inferior alveolar vessels and nerve. The foramen is overlapped in front by a triangular process, the *lingula mandibule*, to the margins of which the sphenomandibular ligament

FIG. 336.—Mandible. Internal surface. Side view.

is attached; behind the lingula is a notch from which the *mylohyoid groove* or *sulcus* runs obliquely downwards and forwards, and lodges the mylohyoid vessels and nerve. Behind this groove is a rough surface, for the insertion of the Pterygoideus internus. Into the anterosuperior part of the medial surface a part of the Temporalis is inserted. The *mandibular canal* runs from the mandibular foramen obliquely downwards and forwards in the ramus, and then horizontally forwards in the body, where it is placed under the alveoli and communicates with them by small openings. It contains the inferior alveolar vessels and nerve, from which branches enter the roots of the teeth. Between the roots of the first and second premolar teeth the mandibular canal divides into the *mental* and *incisive canals*; the mental canal runs upwards, backwards and lateralwards and ends at the mental foramen; the incisive canal is continued forward below the incisor teeth. The *lower border* of the ramus is thick, straight, and continuous with the inferior border of the body of the bone. At its junction with the posterior border is the *angle* of the mandible, which may be either inverted or everted, and is marked by rough, oblique ridges on each side, for the insertion of the Masseter laterally, and the Pterygoideus internus medially; the stylomandibular ligament is attached to the angle, between these muscles. The *anterior border* is thin above, thicker below, and continuous with the oblique line. The *posterior border* is thick, smooth, rounded, and covered by the parotid gland. The *upper border* is thin, and is surmounted

by two processes, the *coronoid* in front and the *condyloid* behind, separated by a deep concavity, the *mandibular notch*, which transmits the *masseteric nerve* and *vessels*.

The *coronoid process* is a thin, triangular eminence, which is flattened from side to side. Its *anterior border* is convex and is continuous below with the anterior border of the ramus; its *posterior border* is concave and forms the anterior boundary of the mandibular notch. Its *lateral surface* is smooth, and affords insertion to the *Masseter* and *Temporalis*. Its *medial surface* gives insertion to the *Temporalis*, and presents a ridge which begins near the apex of the process and runs downwards and forwards to the inner side of the last molar tooth. Between this ridge and the anterior border is a grooved triangular area, the upper part of which gives attachment to the *Temporalis*, the lower part to some fibres of the *Buccinator*.

The *condyloid process* is thicker than the coronoid, and consists of two portions: the *condyle*, and the constricted neck which supports it. The *condyle* articulates with the articular disc of the temporomandibular joint; it is convex from before backwards and from side to side, and its articular surface extends lower on the posterior than on the anterior surface. The long axis of the condyle is directed medialwards and slightly backwards, and if prolonged to the middle line would meet that of the opposite condyle near the anterior margin of the *foramen magnum*. At the lateral extremity of the condyle is a small tubercle for the attachment of the temporomandibular ligament. The *neck* is flattened from before backward, and strengthened by ridges which descend from the front and sides of the condyle. Its posterior surface is convex; on its anterior surface is a depression, the *pterygoid fovea*, for the attachment of the *Pterygoideus externus*.

Ossification.—The mandible is ossified in the fibrous membrane covering the outer surfaces of Meckel's cartilages. These two cartilages, a right and a left, form the cartilaginous bar of the mandibular arch (see p. 77). Their proximal or cranial ends are connected with the cartilaginous ear-capsules, and their distal extremities are joined to one another at the symphysis by mesodermal tissue. They

run forwards immediately below the mandibular condyles and then, bending downwards, lie in a groove near the lower border of the bone; in front of the canine tooth they incline upwards to the symphysis. From the proximal end of each cartilage the malleus and incus, two of the three bones of the middle ear, are developed; the next succeeding portion, as far as the lingula of the mandible,

is replaced by fibrous tissue, which forms the sphenomandibular ligament. Between the lingula and the canine tooth the cartilage disappears, whilst the portion of it below and behind the incisor teeth is ossified and incorporated with this part of the mandible.

Ossification takes place in the membrane covering the outer surfaces of Meckel's cartilages (figs. 337 to 340), and each half of the bone is formed from a single centre* which appears, near the mental foramen, about the sixth week of foetal life. By

FIG. 337.—Mandible of human embryo 24 mm. long. Outer aspect. (From model by Low.)

FIG. 338.—Mandible of human embryo 24 mm. long. Inner aspect. (From model by Low.)

* Low, *Proceedings of the Anatomical and Anthropological Society of the University of Aberdeen*, 1905, and *Journal of Anatomy and Physiology*, vol. xlv., and Fawcett, *Journal of the American Medical Association*, September 2, 1905.

the tenth week the portion of Meckel's cartilage which lies below and behind the incisor teeth is surrounded and invaded by the membrane-bone. Somewhat later, accessory pieces of cartilage make their appearance—viz. a wedge-shaped piece in the condyloid process and extending downwards through the ramus; a small patch along the anterior border of the coronoid process; and smaller nodules in the front part of both alveolar walls and along the front of the lower border of the bone. These accessory nodules of cartilage possess no separate ossific centres, but are invaded by the surrounding membrane-bone and undergo absorption. The inner

FIG. 339.—Mandible of human embryo 95 mm. long. Outer aspect.
(Nuclei of cartilage stippled.) (From model by Low.)

FIG. 340.—Mandible of human embryo 95 mm. long. Inner aspect.
(Nuclei of cartilage stippled.) (From model by Low.)

alveolar border, formerly described as arising from a separate *splanial* centre, is formed in the human mandible by an ingrowth from the main mass of the bone. At birth the bone consists of two parts, united by a fibrous symphysis, in which ossification takes place during the first year.

CHANGES PRODUCED IN THE MANDIBLE BY AGE.

At birth (fig. 341) the body of the bone is a mere shell, containing on either side the sockets of the deciduous teeth, imperfectly partitioned off from one another. The mandibular canal runs near the lower border of the bone, and the mental foramen opens beneath the socket of the first deciduous molar tooth. The angle is obtuse (175°), and the condyloid portion is nearly in line with the body. The coronoid process is relatively large, and projects above the level of the condyle.

After birth (fig. 342) the two segments of the bone become joined at the symphysis, from below upwards, in the first year; but a trace of separation may be visible in the beginning of the second year, near the alveolar margin. The body elongates, but more especially behind the mental foramen, to provide space for the three additional teeth developed in this part. The depth of the body increases by growth of the alveolar part of the bone, to afford room for the roots of the teeth, and by thickening of the sub-alveolar portion. After the second dentition, the mandibular canal is situated just above the level of the mylohyoid line, and the mental foramen occupies the position usual to it in the adult. By the fourth year the angle is reduced to about 140° .

SIDE VIEW OF THE MANDIBLE AT DIFFERENT PERIODS OF LIFE.

FIG. 341.—At birth.

FIG. 342.—In childhood.

FIG. 343.—In the adult.

FIG. 344.—In old age.

In the adult (fig. 343) the alveolar and subalveolar portions of the body are of about equal depth. The mental foramen opens midway between the upper and lower borders of the bone, and the mandibular canal runs nearly parallel with the mylohyoid line. The ramus is almost vertical in direction, the angle measuring from 110° to 120° .

In old age (fig. 344) the bone is reduced in size, for with the loss of the teeth the alveolar process is absorbed, and, consequently, the mandibular canal and the mental foramen are close to the alveolar border. The ramus is oblique in direction, the angle measures about 140° , and the neck of the condyle is more or less bent backwards.

THE HYOID BONE (Os HYOIDEUM)

The hyoid bone (fig. 345) is shaped like a horseshoe, and is suspended from the tips of the styloid processes of the temporal bones by the stylohyoid ligaments. It consists of a body, two greater and two lesser cornua.

The body or central part is of a quadrilateral form. Its anterior surface is convex and directed forwards and upwards. It is crossed in its upper half by a well-marked transverse ridge with a slight downward convexity, and in many cases a vertical median ridge divides it into lateral halves. The portion

FIG. 345.—Hyoid bone. Anterior surface. (Enlarged.)

of the vertical ridge above the transverse line is present in a majority of specimens, but the portion below the transverse line is evident only in rare cases. The anterior surface gives insertion to the Geniohyoideus in the greater part of its extent both above and below the transverse ridge; a portion of the origin of the Hyoglossus notches the lateral margin of the Geniohyoideus attachment. Below the transverse ridge the Mylohyoideus, Sternohyoideus, and Omohyoideus are inserted. The posterior surface is smooth, concave, directed backwards and downwards, and separated from the epiglottis by the hyothyroid membrane and a quantity of loose areolar tissue; a bursa intervenes between it and the membrane. The superior border is rounded, and gives attachment to the hyothyroid membrane and some aponeurotic fibres of the Genioglossus. The inferior border affords insertion medially to the Sternohyoideus and laterally to the Omohyoideus and occasionally a portion of the Thyrohyoideus. It also gives attachment to the Levator glandulae thyroideae, when this muscle is present. In early life the lateral borders of the body are connected to the greater cornua by synchondroses; after middle life usually by bony union.

The greater cornua project backwards from the lateral borders of the body; they are flattened from above downwards and diminish in size from before backwards; each ends in a tubercle to which the lateral hyothyroid ligament is fixed. The upper surface is rough close to its lateral border, for muscular attachments: the largest of these are the origins of the Hyoglossus and Constrictor pharyngis medius which extend along the whole length of the cornu; the Digastricus and Stylohyoideus have small insertions in front of

these near the junction of the body with the cornu. To the *medial border* the hyothyroid membrane is attached, while the anterior half of the *lateral border* gives insertion to the Thyreohyoideus.

The lesser cornua are two small, conical eminences, attached by their bases to the angles of junction between the body and greater cornua. They are connected to the body of the bone by fibrous tissue and occasionally to the greater cornua by diarthrodial joints, which usually persist throughout life, but occasionally become ankylosed.

The lesser cornua are situated in the line of the transverse ridge on the body and appear to be morphological continuations of it (Parsons *). The apex of each cornu gives attachment to the stylohyoid ligament †; the Chondroglossus rises from the medial side of the base.

Ossification.—The hyoid bone is developed from the cartilages of the second and third branchial or visceral arches—the lesser cornua from the second arch, the greater cornua from the third, and the body from the fused ventral ends of both (page 78). It is ossified from six centres: two for the body, and one for each cornu. Ossification commences in the greater cornua towards the end of foetal life, in the body before or shortly after birth, and in the lesser cornua during the first or second year, or later.

EXTERIOR OF THE SKULL

The skull as a whole may be viewed from above (*norma verticalis*), from below (*norma basalis*), from the side (*norma lateralis*), from behind (*norma occipitalis*), or from the front (*norma frontalis*).

NORMA VERTICALIS

When viewed from above, the outline of the skull varies greatly in different specimens; in some it is more or less oval, in others more nearly circular. The surface is traversed by three sutures, viz.: (1) the coronal, nearly transverse in direction, between the frontal and parietal bones; (2) the sagittal, medially placed, between the parietal bones, and deeply serrated in its anterior two-thirds; and (3) the upper part of the lambdoidal, between the parietals and the occipital. The point of junction of the sagittal and coronal sutures is named the bregma, that of the sagittal and lambdoidal sutures, the lambda; they indicate respectively the positions of the anterior and posterior fonticuli in the foetal skull. On either side of the sagittal suture are the parietal tuberosity or eminence and the parietal foramen—the latter, however, is frequently absent on one or both sides. The skull is often somewhat flattened in the neighbourhood of the parietal foramina, and the term *obelion* is applied to that point of the sagittal suture which is on a level with the foramina. At the front is the glabella; lateral to it are the superciliary arches, and above these the frontal tuberosities or eminences. Immediately above the glabella the remains of the frontal suture may be seen; in about 9 per cent. of skulls this suture persists and extends along the middle line to the bregma. Passing backwards and upwards from the zygomatic processes of the frontal bone are the temporal lines, which mark the upper limits of the temporal fossæ. The zygomatic arches may or may not be seen projecting beyond the anterior portions of these lines.

NORMA BASALIS (BASIS CRANII EXTERNA) (fig. 346)

The inferior surface of the base of the skull, exclusive of the mandible, is bounded in front by the incisor teeth in the maxillæ; behind, by the superior nuchal lines of the occipital bone; and laterally by the alveolar arch, the lower border of the zygomatic bone, the zygomatic arch and an imaginary line

* The topography and morphology of the human hyoid bone, by F. G. Parsons, *Journal of Anatomy and Physiology*, vol. xliii.

† These ligaments may undergo partial ossification.

FIG. 346.—Base of skull. Inferior surface.

drawn from the last to the mastoid process and the superior nuchal line of the occipital. The anterior part or hard palate projects below the level of the rest of the surface, and is bounded in front and laterally by the alveolar arch containing the sixteen teeth of the maxillæ. Immediately behind the incisor teeth is the incisive foramen. In this foramen are two lateral apertures, the openings of the incisive canals (foramina of Stensen); each of these leads upwards into the corresponding nasal cavity and transmits the terminal branches of the greater palatine artery and the nasopalatine nerve. Occasionally there are two additional apertures in the middle line; they are termed the foramina of Scarpa, and when present the nasopalatine nerves pass through them instead of through the foramina of Stensen, the left nerve being usually transmitted through the anterior, and the right through the posterior foramen. The vault of the hard palate is concave, uneven, perforated by numerous foramina, marked by depressions for the palatine glands, and traversed by a crucial suture formed by the junction of the four bones of which it is composed. In the young skull a suture may be present, extending on either side from the incisive foramen to the interval between the lateral incisor and canine teeth, and marking off in front of it the os incisivum or premaxillary bone. At either posterior angle of the hard palate is the greater palatine foramen, for the transmission of the greater palatine vessels and anterior palatine nerve; and running forwards and medialwards from it are two grooves, for the same vessels and nerve. Behind the greater palatine foramen is the pyramidal process of the palatine bone, perforated by two or three lesser palatine foramina, and marked by the beginning of a curved ridge for the attachment of part of the aponeurosis of the Tensor veli palatini. Projecting backwards from the middle of the posterior border of the hard palate is the posterior nasal spine, from which the Musculus uvula takes origin.

Behind and above the hard palate are the choanæ, measuring about 2.5 cm. vertically and 1.25 cm. transversely. They are separated from one another by the vomer and each is bounded above by the body of the sphenoidal bone and the vaginal process of the medial pterygoid lamina, below by the horizontal part of the palatine bone, and laterally by the medial pterygoid lamina. At the superior border of the vomer are the expanded ends of this bone, which receive between them the rostrum of the sphenoidal bone, and articulate laterally with the sphenoidal processes of the palatine bones and the vaginal processes of the medial pterygoid lamina. Above the vaginal processes are the pharyngeal canals. The medial pterygoid lamina is long and narrow; lateral to its upper part is the scaphoid fossa, for the origin of the Tensor veli palatini. At the upper end of the medial pterygoid lamina is the pterygoid tubercle, and immediately above this tubercle, the posterior end of the pterygoid canal; at the lower end of the lamina is the hamulus, around which the tendon of the Tensor veli palatini turns. The lateral pterygoid lamina is broad; its lateral surface forms the medial boundary of the infratemporal fossa, and gives origin to the Pterygoideus externus.

Behind the choanæ is the basilar portion of the occipital bone; near its centre is the pharyngeal tubercle for the attachment of the fibrous raphe of the pharynx, and on either side of the middle line are depressions for the insertions of the Rectus capitis anterior and Longus capitis. Immediately behind the upper end of the lateral pterygoid lamina is the foramen ovale, for the transmission of the mandibular nerve, the accessory meningeal artery, and sometimes the lesser superficial petrosal nerve; behind this are the foramen spinosum and the spina angularis of the sphenoidal bone; the former transmits the middle meningeal artery and the nervus spinosus, the latter gives attachment to the sphenomandibular ligament and the Tensor veli palatini. Lateral to the spina angularis is the mandibular fossa, divided into two parts by the petrotympanic fissure; the anterior portion of the fossa, concave, smooth and bounded in front by the articular tubercle, articulates with the articular disc of the temporomandibular joint; the posterior portion, bounded behind by the tympanic part of the temporal bone, is sometimes occupied by a part of the parotid gland. Emerging from the vagina processus styloidei of the tympanic part is the styloid process; and behind the upper end of this process is the stylomastoid foramen, for the exit of the facial nerve, and entrance

of the stylomastoid artery. Lateral to the stylomastoid foramen, between the tympanic part and the mastoid process, is the tympanomastoid fissure, which gives exit to the auricular branch of the vagus nerve. Medial to the mastoid process is the mastoid notch for the posterior belly of the Digastricus, and medial to the mastoid notch, the groove for the occipital artery. At the base of the medial pterygoid lamina is the foramen lacerum, bounded anteriorly by the great wing of the sphenoidal bone, posteriorly and laterally by the apex of the petrous portion of the temporal bone, and medially by the body of the sphenoidal bone and basilar portion of the occipital bone; it presents in front the posterior orifice of the pterygoid canal; behind, the aperture of the carotid canal. In the recent state the lower part of the foramen lacerum is filled up by a fibrocartilaginous plate, on the upper surface of which the internal carotid artery rests. Lateral to the foramen lacerum is the sulcus tubæ auditivæ, between the petrous part of the temporal bone and the great wing of the sphenoidal bone. This sulcus, directed lateralwards and backwards, lodges the cartilaginous part of the auditory tube, and is continuous behind with the semicanalis tubæ auditivæ in the temporal bone. In the floor of this sulcus is the petrosphenoidal fissure, occupied, in the recent condition, by a plate of cartilage. Behind this fissure is the under surface of the petrous portion of the temporal bone, presenting, near its apex, a quadrilateral rough surface, part of which gives origin to the Levator veli palatini; lateral to this surface is the orifice of the carotid canal, and medial to the canal, the depression leading to the aquæductus cochleæ, the former transmitting the internal carotid artery and the carotid plexus of the sympathetic, the latter serving for the passage of a vein from the cochlea. Behind the carotid canal is the jugular foramen, formed in front and laterally by the petrous portion of the temporal bone, behind and medially by the occipital bone; it is generally larger on the right than on the left side, and may be subdivided into three parts. The anterior part transmits the inferior petrosal sinus; the intermediate, the glossopharyngeal, vagus, and accessory nerves; the posterior, the transverse sinus and some meningeal branches from the occipital and ascending pharyngeal arteries. On the ridge of bone between the carotid canal and the jugular foramen is the inferior tympanic canaliculus for the transmission of the tympanic branch of the glossopharyngeal nerve; in the lateral part of the jugular foramen, near the root of the styloid process, is the mastoid canaliculus for the passage of the auricular branch of the vagus nerve. Running between the jugular foramen and the foramen lacerum is the petro-occipital fissure, occupied, in the recent state, by a plate of cartilage. Behind the basilar portion of the occipital bone is the foramen magnum which transmits the medulla oblongata and its membranes, the spinal parts of the accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, and the ligaments connecting the occipital bone with the axis. Lateral to the anterior half of the foramen magnum are the occipital condyles for articulation with the atlas vertebra; the medial side of each condyle is rough for the attachment of the alar ligament. Lateral to the condyle is the jugular process, which gives attachment to the Rectus capitis lateralis. In front of the condyle is the hypoglossal canal for the passage of the hypoglossal nerve and a meningeal artery. Behind the condyle is the condyloid fossa, which is sometimes perforated by the condyloid canal, for the transmission of a vein from the transverse sinus. Behind the foramen magnum is the median nuchal line, ending above at the external occipital protuberance; on either side are the superior and inferior nuchal lines, which, with the surfaces of bone between them, are rough for the attachment of the muscles enumerated on p. 193.

NORMA LATERALIS (fig. 347)

When viewed from the side the skull is seen to consist of the cranium above and behind, and the face below and in front. The cranium is somewhat ovoid in shape, but its contour varies in different cases and depends largely on the length and height of the skull and on the degree of prominence of the superciliary arches and frontal tuberosities. Entering into its formation are the frontal, parietal, occipital, temporal, and sphenoidal bones. These bones are joined

to one another by the coronal, squamosal, parietomastoid, lambdoidal, sphenofrontal, sphenoparietal and sphenosquamosal sutures. The sphenoparietal suture varies in length in different skulls, and is absent in those cases where the frontal articulates with the temporal squama; the posterior end of the sphenoparietal suture is named the pterion. The squamosal suture arches backwards from the pterion and connects the temporal squama with the lower border of the parietal bone; it is continuous behind with the short, nearly horizontal parietomastoid suture, which unites the mastoid process of the temporal bone with the region of the mastoid angle of the parietal bone. Extending from above downwards and forwards across the cranium are the

FIG. 347.—Side view of skull.

coronal and lambdoidal sutures; the former connects the parietal bones with the frontal bone; the latter, the parietal bones with the occipital bone. The lambdoidal suture is continuous below with the occipitomastoid suture between the occipital bone and the mastoid portion of the temporal bone; in or near this suture is the mastoid foramen which transmits an emissary vein.

Immediately above the orbital margin is the superciliary arch, and, at a higher level, the frontal tuberosity. Near the centre of the parietal bone is the parietal tuberosity. Posteriorly is the external occipital protuberance, from which the superior nuchal line may be followed to the mastoid process. The temporal lines arch across the side of the cranium and mark the upper limit of the temporal fossa.

The temporal fossa is bounded above and behind by the temporal lines, which extend from the zygomatic process of the frontal bone upwards and backwards across the frontal and parietal bones, and then curve downwards

and forwards to the temporal bone to become continuous with the supra-mastoid crest and the posterior root of the zygomatic arch. The temporal fossa is bounded in front by the frontal and zygomatic bones ; opening on the latter is the zygomaticotemporal foramen. Laterally the fossa is limited by the zygomatic arch ; below, it is separated from the infratemporal fossa by the infratemporal crest on the great wing of the sphenoidal bone, and by a ridge which runs backwards from this crest across the temporal squama to the anterior root of the zygomatic process. The floor of the fossa, deeply concave in front, is formed by the zygomatic, frontal, parietal, sphenoidal, and temporal bones. It is traversed by vascular furrows : one, usually well marked, runs upwards above the opening of the external acoustic meatus, and lodges the middle temporal artery. Two others, frequently indistinct, may be observed on the anterior part of the floor, and are for the anterior and posterior deep temporal arteries. The temporal fossa contains the Temporalis muscle and its vessels and nerves, together with the zygomaticotemporal nerve.

The zygomatic arch is formed by the union of the zygomatic process of the temporal bone with the temporal process of the zygomatic bone ; the tendon of the Temporalis descends on the medial side of the arch to gain insertion into the coronoid process of the mandible. The zygomatic process of the temporal arises by two roots, an anterior, directed inwards in front of the mandibular fossa, where it expands to form the articular tubercle, and a posterior which runs backwards above the opening of the external acoustic meatus and is continuous with the supramastoid crest. The upper border of the arch gives attachment to the temporal fascia ; the lower border and medial surface give origin to the Masseter.

Below the posterior root of the zygomatic arch is the elliptical opening (porus acusticus externus) of the external acoustic meatus, bounded in front, below, and behind by the tympanic part of the temporal bone : to its circumference the cartilaginous segment of the external acoustic meatus is attached. The small triangular area between the posterior root of the zygomatic arch and the posterosuperior part of the porus acusticus is termed the suprameatal triangle, on the anterior border of which a small spinous process, the suprameatal spine, is sometimes seen. Between the tympanic part and the articular tubercle is the mandibular fossa ; behind the fossa the styloid process extends downwards and forwards for a variable distance, and gives attachment to the Styloglossus, Stylohyoideus, and Stylopharyngeus muscles, and to the stylohyoid and stylomandibular ligaments. Projecting downwards behind the porus acusticus externus is the mastoid process, to the outer surface of which the Sternocleidomastoideus, Splenius capitis, and Longissimus capitis are attached.

The *infratemporal fossa* (fig. 348) is an irregularly shaped space, situated below, and medial to, the zygomatic arch. It is bounded in front by the infratemporal surface of the maxilla, and the ridge which extends from its zygomatic process ; behind, by the articular tubercle of the temporal bone and the spina angularis of the sphenoidal bone ; above, by the great wing of the sphenoidal bone below the infratemporal crest, and by the under surface of the temporal squama ; below, by the alveolar border of the maxilla ; medially, by the lateral pterygoid lamina. It contains the lower part of the Temporalis, the Pterygoidei internus and externus, the internal maxillary vessels, and the mandibular and maxillary nerves. The foramen ovale and foramen spinosum open on its roof, and the alveolar canals, on its anterior wall. At its upper and medial part are two fissures, which together form a rectangular fissure, the horizontal limb being the inferior orbital, and the vertical one the pterygo-maxillary.

The *inferior orbital fissure* (sphenomaxillary fissure), nearly horizontal in direction, opens into the lateral and back part of the orbit. It is bounded above by the lower border of the orbital surface of the great wing of the sphenoidal bone ; below, by the lateral border of the orbital surface of the maxilla and the orbital process of the palatine bone ; laterally, by a small part of the zygomatic bone* ; medially, it joins at right angles with the pterygomaxillary fissure. Through the inferior orbital fissure the orbit communicates with the infra-

* Sometimes the maxilla and the sphenoidal bone articulate with each other at the lateral extremity of this fissure ; the zygomatic is then excluded from it.

temporal and pterygopalatine fossæ; the fissure transmits the maxillary nerve and its zygomatic (temporomalar) branch, the infraorbital vessels, the orbital branches of the sphenopalatine ganglion, and a vein which connects the inferior ophthalmic vein with the pterygoid venous plexus.

The pterygomaxillary fissure is vertical, and descends at right angles from the medial end of the preceding; it is a triangular interval, formed by the divergence of the maxilla from the pterygoid process of the sphenoidal bone. It connects the infratemporal with the pterygopalatine fossa, and transmits the terminal part of the internal maxillary artery.

FIG. 348.—Left infratemporal fossa.

The pterygopalatine fossa (sphenomaxillary fossa) (fig. 351) is a small, triangular space at the angle of junction of the inferior orbital and pterygomaxillary fissures, and placed beneath the apex of the orbit. It is bounded above by the under surface of the body of the sphenoidal bone and by the orbital process of the palatine bone; in front, by the upper part of the infratemporal surface of the maxilla; behind, by the base of the pterygoid process and lower part of the anterior surface of the great wing of the sphenoidal bone; medially, by the vertical part of the palatine bone with its orbital and sphenoidal processes. The fossa contains the maxillary nerve, the sphenopalatine ganglion and the terminal part of the internal maxillary artery. Five foramina open into it. Of these, three are on the posterior wall, viz.: the foramen rotundum, the pterygoid canal, and the pharyngeal canal, in this order downwards and medialwards; on the medial wall is the sphenopalatine foramen; below is the superior orifice of the pterygopalatine canal.

NORMA OCCIPITALIS

When viewed from behind, the cranium presents a more or less circular outline. In the middle line above is the posterior part of the sagittal suture connecting the parietal bones; extending downwards and lateralwards from

the posterior end of this suture is the deeply serrated lambdoidal suture joining the parietals to the occipital and continuous below with the parietomastoid and occipitomastoid sutures; it frequently contains one or more sutural bones. Near the middle of the occipital squama is the external occipital protuberance or inion, and, extending lateralwards from it, the superior nuchal lines, and above these the faintly marked highest nuchal lines. The outer surface of the part of the occipital bone above the inion and highest nuchal lines is named the planum occipitale, and is covered by the Occipitalis muscle; the outer surface of the part below is termed the planum nuchale, and is divided by the medial nuchal line which runs downwards and forwards from the inion to the foramen magnum; this line gives attachment to the ligamentum nuchæ. The muscles attached to the planum nuchale are enumerated on p. 193. Below and in front are the mastoid processes, convex laterally and grooved medially by the mastoid notches. In or near the occipitomastoid suture is the mastoid foramen for the passage of the mastoid emissary vein.

NORMA FRONTALIS (fig. 349)

When viewed from the front, the skull exhibits a somewhat oval outline, limited above by the frontal bone, below by the body of the mandible, and laterally by the zygomatic bones and the mandibular rami. The upper part, formed by the frontal squama, is smooth and convex. The lower part, made up of the bones of the face, is irregular; it is excavated laterally by the orbital cavities, and presents in the middle the anterior nasal aperture leading to the nasal cavities, and below this the transverse slit between the upper and lower dental arcades. The frontal tuberosities stand out more or less prominently, and beneath these are the superciliary arches, the medial ends of which are joined to one another by the glabella. On and above the glabella a trace of the frontal suture sometimes persists; beneath the glabella is the frontonasal suture, below and behind which are the frontomaxillary and frontolacrimal sutures. Below each superciliary arch is the upper part of the margin of the base of the orbit, thin and prominent in its lateral two-thirds, rounded in its medial third, and displaying at the junction of these two portions the supraorbital notch or foramen for the supraorbital nerve and vessels. The supraorbital margin ends laterally in the zygomatic process, from which the temporal lines extend upwards and backwards. Below the frontonasal suture is the bridge of the nose, convex from side to side, concavo-convex from above downwards, and formed by the two nasal bones supported in the middle line by the nasal spine of the frontal and the lamina perpendicularis of the ethmoidal bone. The frontal processes of the maxillæ ascend between the nasal and lacrimal bones and form the lower and medial parts of the circumferences of the orbits. Below the nasal bones and between the maxillæ is the anterior aperture of the nasal cavity, pyriform in shape, with the narrow end directed upwards. Laterally this aperture is bounded by sharp margins which curve medialwards and forwards and end in the anterior nasal spine. On looking into the nasal cavity, the bony septum between the right and left nasal chambers presents, in front, a large triangular deficiency; this is filled in the recent state by the cartilage of the nasal septum; on the lateral wall of each nasal cavity the anterior part of the inferior nasal concha is visible. Below and lateral to the anterior nasal aperture are the anterior surfaces of the maxillæ, each perforated, near the lower margin of the orbit, by the infraorbital foramen for the passage of the infraorbital nerve and vessels. Below and medial to this foramen is the canine eminence separating the incisive from the canine fossa. Beneath these fossæ are the alveolar processes of the maxillæ containing the upper teeth, which overlap the teeth of the mandible in front. The zygomatic bone on either side forms the prominence of the cheek, the lower and lateral portion of the orbital cavity, and the anterior part of the zygomatic arch. It articulates medially with the maxilla, behind with the zygomatic process of the temporal bone, and the great wing of the sphenoidal bone, and above with the zygomatic process of the frontal bone; it is perforated by the zygomaticofacial foramen for the passage of the zygomaticofacial nerve. On the upper part of the body of the mandible is a median ridge, indicating the position of the symphysis;

this ridge divides below to enclose the mental protuberance, the lateral angles of which constitute the mental tubercles. Below the incisor teeth is the incisive fossa, and beneath the second premolar tooth the mental foramen which transmits the mental nerve and vessels. The oblique line ascends from the mental tubercle and is continuous behind with the anterior border of the ramus. The posterior border of the ramus runs downwards and forwards from the condyle to the angle, which is frequently more or less everted.

FIG. 349.—The skull from the front.

The orbits (fig. 349) are two quadrilateral pyramidal cavities, situated at the upper and anterior part of the face, their bases being directed forwards and lateralwards, and their apices backwards and medialwards, so that their long axes, if continued backwards, would meet over the body of the sphenoidal bone. Each has a roof, a floor, a medial and a lateral wall, a base, and an apex.

The roof of the orbit is concave, directed downwards and slightly forwards, and formed in front by the orbital plate of the frontal bone, behind by the small wing of the sphenoidal bone. It presents, just within the base of the orbit and about midway between the supraorbital notch and the frontolacrimal suture, a small depression or spine, the fovea vel spina trochlearis, for the attachment of the cartilaginous pulley of the Obliquus oculi superior; on its

anterolateral part is the lacrimal fossa for the lacrimal gland ; posteriorly is the suture between the frontal bone and the small wing of the sphenoidal bone.

The floor of the orbit (fig. 350) looks upwards and lateralwards, and is of less extent than the roof ; it is formed chiefly by the orbital surface of the maxilla : in front and laterally, by the orbital process of the zygomatic bone ; behind and medially, to a small extent, by the orbital process of the palatine bone. At its medial angle is the upper opening of the nasolacrimal canal, immediately to the lateral side of which is a depression for the origin of the Obliquus oculi inferior. On its lateral part is the suture between the maxilla

FIG. 350.—Horizontal section of nasal and orbital cavities, viewed from above.

and zygomatic bone, and at its posterior part that between the maxilla and the orbital process of the palatine bone. Running forwards near the middle of the floor is the infraorbital groove, ending anteriorly in the infraorbital canal and transmitting the infraorbital nerve and vessels.

The medial wall of the orbit (fig. 351) is nearly vertical, and is formed from before backwards by the frontal process of the maxilla, the lacrimal, the lamina papyracea of the ethmoidal bone, and a small portion of the body of the sphenoidal bone in front of the optic foramen ; sometimes the sphenoidal concha forms a small part of this wall (see p. 202). It exhibits three vertical sutures—viz. : the lacrimomaxillary, lacrimo-ethmoidal, and speno-ethmoidal. In front is seen the lacrimal fossa, which lodges the lacrimal sac, and behind the fossa is the posterior lacrimal crest, from which the lacrimal part of the Orbicularis oculi arises. At the junction of the medial wall and the roof are the frontomaxillary, frontolacrimal, fronto-ethmoidal, and frontosphenoidal sutures. In the fronto-ethmoidal suture are the anterior and posterior ethmoidal foramina, the former transmitting the anterior ethmoidal nerve and vessels, the latter the posterior ethmoidal nerve and vessels.

The *lateral wall* of the orbit, directed medialwards and forwards, is formed by the orbital surface of the zygomatic bone and the orbital surface of the great wing of the sphenoidal bone; these are united by the sphenozygomatic suture which terminates below at the anterior end of the inferior orbital fissure. On the orbital process of the zygomatic bone are the orbital tubercle (Whitnall) and the orifices of one or two canals which transmit the branches of the zygomatic nerve. Between the roof and the lateral wall, near the apex of the orbit, is the superior orbital fissure. Through this fissure the oculomotor, the trochlear, the ophthalmic, and the abducent nerves enter the orbital cavity, also some filaments from the cavernous plexus of the sympathetic and the

FIG. 351.—Medial wall of left orbit.

orbital branches of the middle meningeal artery. The ophthalmic veins and the recurrent branch from the lacrimal artery to the dura mater leave the orbit through this fissure. The lateral wall and the floor of the orbit are separated posteriorly by the inferior orbital fissure which transmits the maxillary nerve and its zygomatic branch, the infraorbital vessels, and the ascending branches of nerves from the sphenopalatine ganglion.

The *base* of the orbit, quadrilateral in shape, is formed above by the supra-orbital arch of the frontal bone, in which is the supraorbital notch or foramen for the passage of the supraorbital vessels and nerve; below by the zygomatic bone and maxilla, united by the zygomaticomaxillary suture; laterally by the zygomatic bone and the zygomatic process of the frontal bone joined by the zygomaticofrontal suture; medially by the frontal bone and the frontal process of the maxilla united by the frontomaxillary suture.

The *apex* of the orbit corresponds to the optic foramen,* a short canal, through which the optic nerve and ophthalmic artery enter the orbital cavity.

* Some anatomists describe the apex of the orbit as corresponding with the medial end of the superior orbital fissure. It seems better, however, to adopt the statement in the text, since the Recti muscles take origin around the optic foramen, and diverge from it to the bulb of the eye.

INTERIOR OF THE SKULL

In order to study the interior of the skull, the skull-cap should be removed by a saw-cut carried round the cranium about the level of the frontal eminences and the upper limits of the squamosal sutures, cutting the occipital bone about 2.5 cm. above the external protuberance.

INNER SURFACE OF THE SKULL-CAP

On the concave inner surface of the skull-cap are depressions for the convolutions of the cerebrum and numerous furrows for the branches of the meningeal vessels. In the middle line is the sagittal sulcus, narrow in front, and broad behind; it lodges the superior sagittal sinus, and its margins afford attachment to the falx cerebri. On either side of it are several depressions for the arachnoideal granulations, and, at its posterior part, the openings of the parietal foramina when these are present. It is crossed in front by the coronal suture, and behind by the lambdoidal suture, whilst the sagittal suture lies in the median plane between the parietal bones.

UPPER SURFACE OF THE BASE OF THE SKULL (BASIS CRANII INTERNA) (fig. 352)

The upper surface of the base of the skull, or floor of the cranial cavity, is divided into anterior, middle, and posterior cranial fossæ.

Anterior fossa.—The floor of this fossa is formed by the orbital plates of the frontal bone, the lamina cribrosa of the ethmoidal bone, the small wings and anterior part of the body of the sphenoidal bone; it is limited behind by the posterior borders of the small wings of the sphenoidal bone and by the anterior margin of the sulcus chiasmatis. It is traversed by the fronto-ethmoidal, spheno-ethmoidal and sphenofrontal sutures. Its lateral portions roof in the orbital cavities and support the frontal lobes of the cerebrum; they are convex and marked by depressions for the brain convolutions, and by grooves for branches of the meningeal vessels. The central portion corresponds with the roof of the nasal cavity, and is markedly depressed on either side of the crista galli. It presents, in the median line, from before backwards, the commencement of the frontal crest for the attachment of the falx cerebri; the foramen cæcum, which usually transmits a small vein from the nasal cavity to the superior sagittal sinus; the crista galli, the free margin of which affords attachment to the anterior end of the falx cerebri. On either side of the crista galli is the olfactory groove formed by the lamina cribrosa of the ethmoidal bone, which supports the olfactory bulb and is perforated by foramina for the transmission of the olfactory nerves; at the front part of this lamina is the foramen for the anterior ethmoidal nerve. Lateral to either olfactory groove are the internal openings of the anterior and posterior ethmoidal foramina; the anterior, situated about the middle of the lateral margin of the olfactory groove, transmits the anterior ethmoidal nerve and vessels; the nerve runs in a groove along the lateral edge of the lamina cribrosa to the foramen above mentioned; the posterior ethmoidal foramen opens at the posterior part of this margin under cover of a projecting lamina of the sphenoidal bone, and transmits the posterior ethmoidal nerve and vessels. Posteriorly the anterior margin of the sulcus chiasmatis runs lateralwards to the upper margins of the optic foramina.

The middle fossa, deeper than the preceding, is narrow in the middle, and wide at the sides of the skull. It is bounded in front by the posterior margins of the small wings of the sphenoidal bone, the anterior clinoid processes, and the ridge forming the anterior margin of the sulcus chiasmatis; behind, by the dorsum sellæ of the sphenoidal bone and the superior angles of the petrous portions of the temporals; laterally by the temporal squamæ, the sphenoidal angles of the parietal bones, and the great wings of the sphenoidal bone. It is traversed by the squamosal, sphenoparietal, sphenosquamosal, and sphenopetrous sutures.

The middle part of the fossa presents, in front, the sulcus chiasmatis and tuberculum sellæ; the sulcus ends on either side at the optic foramen, which

FIG. 352.—Base of the skull. Upper surface.

transmits the optic nerve and ophthalmic artery to the orbital cavity. Behind the optic foramen the anterior clinoid process is directed backwards and medialwards and gives attachment to the tentorium cerebelli. Behind the tuberculum sellæ is a deep depression, the sella turcica, containing the fossa hypophyseæ.

which lodges the hypophysis, and presents at the lateral angles of its anterior wall the middle clinoid processes. The sella turcica is bounded posteriorly by the dorsum sellæ, the upper angles of which are surmounted by the posterior clinoid processes: these afford attachment to the tentorium cerebelli, and some little distance below each is a notch on the side of the dorsum sellæ for the abducent nerve. Lateral to the sella turcica is the carotid sulcus, which begins behind at the foramen lacerum, and ends on the medial side of the anterior clinoid process, where it is sometimes converted into a foramen (carotico-clinoid) by the union of the anterior and middle clinoid processes; the posterior part of the sulcus is bounded anterolaterally by the lingula. The carotid sulcus lodges the cavernous sinus and the internal carotid artery, the latter being surrounded by a plexus of sympathetic nerves.

The lateral parts of the middle fossa are deep, and support the temporal lobes of the brain. They are marked by deep depressions for the brain convolutions, and traversed by furrows for the anterior and posterior branches of the middle meningeal vessels. These furrows begin by the bifurcation of a groove which runs for about 2 cm. forwards and lateralwards from the foramen spinosum; the anterior furrow is directed forwards and upwards to the sphenoidal angle of the parietal bone, where it is sometimes converted into a bony canal; the posterior arches backwards across the temporal squama and passes on to the parietal bone near the middle of its lower border. The following apertures are also present. In front is the superior orbital fissure, bounded above by the small wing, below by the great wing and medially by the body of the sphenoidal bone; it is usually completed laterally by the orbital plate of the frontal bone. It transmits to the orbital cavity the oculomotor, the trochlear, the ophthalmic division of the trigeminal, and the abducent nerves, some filaments from the cavernous plexus of the sympathetic, and the orbital branch of the middle meningeal artery; and from the orbital cavity a recurrent branch from the lacimal artery to the dura mater, and the ophthalmic veins. Behind the medial end of the superior orbital fissure is the foramen rotundum, for the passage of the maxillary nerve. Posterior and lateral to the foramen rotundum is the foramen ovale, which transmits the mandibular nerve, the accessory ophthalmic artery, and the lesser superficial petrosal nerve.* Medial to the foramen ovale is the foramen Vesalii, which varies in size, and is often absent; when present, it opens below at the lateral side of the scaphoid fossa, and transmits a small vein. Lateral to the foramen ovale is the foramen spinosum, for the passage of the nervus spinosus and the middle meningeal artery. Medial to the foramen ovale is the foramen lacerum; in the recent state the lower part of this foramen is filled by a fibrocartilaginous plate, on the upper surface of which rests the internal carotid artery, surrounded by a plexus of sympathetic nerves, the nerve of the pterygoid canal, and a meningeal branch from the ascending pharyngeal artery, pierce the fibrocartilaginous plate. On the anterior surface of the petrous portion of the temporal bone is the eminentia arcuata caused by the upward projection of the superior semicircular canal; in front of and a little lateral to this, a depressed area forming the roof of the tympanic cavity; the groove leading to the hiatus of the facial canal, for the transmission of the greater superficial petrosal nerve and the petrosal branch of the middle meningeal artery; lateral to it, the smaller groove for the passage of the lesser superficial petrosal nerve; and, near the apex of the bone, the depression for the semilunar ganglion, and the orifice of the carotid canal.

The posterior fossa, the largest and deepest, is formed by the dorsum sellæ of the sphenoidal bone, the basilar and lateral parts of the occipital bone, the petrous and mastoid portions of the temporal bones, the mastoid angles of the parietal bones, and the lower part of the squama occipitalis; it lodges the cerebellum, pons, and medulla oblongata, and is crossed by the petro-occipital, occipitomastoid, and parietomastoid sutures. It is separated from the middle fossa in and near the median line by the dorsum sellæ of the sphenoidal bone, and on either side by the superior angle of the petrous portion of the temporal bone. This angle gives attachment to the tentorium cerebelli, is grooved for the superior petrosal sinus, and is notched at its medial end for the trigeminal nerve. The posterior fossa is limited behind

* See footnote, p. 200.

by the transverse sulci of the occipital bone. In its centre is the foramen magnum, and on either side of this foramen is a rough tubercle for the attachment of the alar ligaments; a little above this tubercle is the hypoglossal canal which transmits the hypoglossal nerve and a meningeal branch from the ascending pharyngeal artery. In front of the foramen magnum the basilar portion of the occipital bone and the posterior part of the body of the sphenoidal bone form the *clivus* which supports the medulla oblongata and pons; in the young skull these bones are joined by a *synchondrosis*. This grooved surface is separated on either side from the petrous portion of the temporal bone by the petro-occipital fissure, which is occupied in the recent state by a plate of cartilage; the fissure is continuous behind with the jugular foramen, and its margins are grooved for the inferior petrosal sinus. The jugular foramen is situated between the lateral part of the occipital bone and the petrous part of the temporal bone. The anterior portion of this foramen transmits the

FIG. 353.—Sagittal section of skull.

inferior petrosal sinus; the posterior portion, the transverse sinus and some meningeal branches from the occipital and ascending pharyngeal arteries; and the intermediate portion, the glossopharyngeal, vagus, and accessory nerves. Above the jugular foramen is the opening of the internal acoustic meatus, for the facial and acoustic nerves and internal auditory artery; behind and lateral to this opening is the slit leading to the aquæductus vestibuli, which lodges the ductus endolymphaticus; while between these, and near the superior angle of the petrous portion, is a small triangular depression, the remains of the fossa subarcuata, which lodges a process of the dura mater and occasionally transmits a small vein. Behind the foramen magnum is the internal occipital crest which serves for the attachment of the falx cerebelli; in the attached margin of this falx is the occipital sinus, which is sometimes duplicated. Lateral to the crest are the inferior occipital fossæ which support the hemispheres of the cerebellum and are limited behind by the transverse sulci. Each of the transverse sinuses, in its passage to the jugular foramen, grooves the occipital bone, the mastoid angle of the parietal bone, the mastoid portion of the temporal bone, and the jugular process of the occipital bone, and ends at the posterior part of the jugular foramen. Where the sinus grooves the mastoid portion

of the temporal bone, the orifice of the mastoid foramen may be seen; and just behind the jugular foramen, the condyloid canal opens into it; neither opening is constant.

THE NASAL CAVITIES

The **nasal cavities** are two irregular spaces, situated one on either side of the middle line of the face, extending from the base of the cranium to the roof of the mouth, and separated from each other by a thin vertical septum. They open on the face through the pear-shaped anterior nasal aperture, and their posterior openings, or choanæ, communicate, in the recent state, with the nasal part of the pharynx. They are much narrower above than below, and in the middle than at their anterior or posterior openings: their depth

FIG. 354.—Medial wall of left nasal cavity.

is greatest in the middle. They communicate with the frontal, ethmoidal, sphenoidal, and maxillary sinuses. Each cavity has a roof, a floor, a medial and a lateral wall.

The *roof* (figs. 354, 355) is horizontal in its central part, but slopes downwards in front and behind; it is formed in front by the nasal bone and the frontal spine; in the middle, by the lamina cribrosa of the ethmoidal bone; and behind, by the body of the sphenoidal bone, the sphenoidal concha, the ala of the vomer and the sphenoidal process of the palatine bone. In the lamina cribrosa are the foramina for the olfactory nerves, and in front of these is the foramen for the anterior ethmoidal nerve; on the posterior part of the roof is the opening into the sphenoidal sinus.

The *floor*, flattened from before backwards and concave from side to side, is formed by the palatine process of the maxilla and the horizontal part of the palatine bone; near its anterior end is the opening of the incisive canal.

The *medial wall*, or *septum nasi* (fig. 354), is frequently deflected to one or other side, more often to the left than to the right. It is formed, in front, by the crest of the nasal bones and the frontal spine; in the middle, by the lamina perpendicularis of the ethmoidal bone; behind, by the vomer and by the

strum of the sphenoidal bone ; below, by the crest of the maxillæ and palatine bones. In front is a large, triangular notch which is filled by the cartilage of the septum ; behind, is the free edge of the vomer. Its surface is marked by furrows for vessels and nerves, and the vomer is grooved for the nasopalatine nerve.

The *lateral wall* (fig. 355) is formed, in front, by the nasal bone, the frontal process of the maxilla, and the lacrimal bone ; in the middle, by the ethmoidal bone, maxilla, and inferior nasal concha ; behind, by the vertical part of the palatine bone, and the medial pterygoid lamina of the sphenoidal bone. On this wall are three irregular, anteroposterior passages, termed the superior, middle, and inferior meatuses of the nose. The superior meatus, the smallest of the three, occupies the middle third of the lateral wall. It lies between the superior and middle nasal conchæ ; the sphenopalatine foramen opens into

FIG. 355.—Roof, floor, and lateral wall of left nasal cavity.

it behind, and the posterior ethmoidal cells in front. Above and behind the superior concha is a triangular depression named the sphenothmoidal recess, into which the sphenoidal sinus opens. The middle meatus is situated between the middle and inferior conchæ, and extends from the anterior to the posterior end of the latter. The lateral wall of this meatus can be satisfactorily studied only after the removal of the middle concha. On it is a curved fissure, the *hiatus semilunaris*, limited below by the edge of the uncinate process of the ethmoidal bone, and above by an elevation named the *bulla ethmoidalis* ; the middle ethmoidal cells are contained within this bulla and open on, or near to it. Through the hiatus semilunaris the meatus opens into a curved passage termed the *infundibulum* ; this communicates in front with the anterior ethmoidal cells, and in rather more than fifty per cent. of skulls is continuous above with the frontonasal duct which opens into the frontal air-sinus ; when this continuity fails through the fusion of the bulla ethmoidalis with the uncinate process of the ethmoidal bone, the frontonasal duct opens directly into the anterior part of the meatus. Below the bulla ethmoidalis and hidden by the uncinate process of the ethmoidal bone is the *ostium maxillare* or opening of the maxillary sinus ; an accessory opening from the sinus is frequently

present above the posterior part of the inferior nasal concha. The *inferior meatus*, the largest of the three, is the space between the inferior concha and the floor of the nasal cavity. It extends almost the entire length of the lateral wall of the nose, is broader in front than behind, and presents anteriorly the lower orifice of the nasolacrimal canal.

The *apertura piriformis*, or *anterior nasal aperture* (fig. 350), is bounded above by the inferior borders of the nasal bones; laterally by the thin, sharp margins which separate the anterior from the nasal surfaces of the maxillæ; and below by the same borders, where they curve medialwards to join each other at the anterior nasal spine. In the recent state it is much contracted by the lateral and alar cartilages of the nose.

The *choana* or *posterior nasal apertures* are each bounded above by the ala of the vomer and the vaginal process of the medial pterygoid lamina; below, by the posterior border of the horizontal part of the palatine bone; laterally, by the medial pterygoid lamina; they are separated from each other by the posterior border of the vomer.

DIFFERENCES IN THE SKULL DUE TO AGE

At birth the skull is large in proportion to the other parts of the skeleton, but the base is short and narrow in proportion to the vault; the facial portion is small and equals only about one-eighth of the bulk of the cranium as compared with one-half in the adult. The frontal and parietal tuberosities or eminences are prominent, and when the skull is viewed from above it presents a pentagonal outline with its

FIG. 356.—Skull at birth, showing frontal and occipital fonticuli.

greatest width at the parietal tuberosities; on the other hand, the glabella, superciliary arches, and mastoid processes are not developed. Ossification of the skull bones is not completed, and many of them—e.g. the occipital, temporals, sphenoidal, frontal, and mandible—consist of more than one piece. Unossified membranous intervals, termed fonticuli (fontanelles), are seen at the angles of the parietal bones; these fonticuli are six in number: two, the frontal and occipital, are situated in the middle line, and two, the sphenoidal and mastoid, on either side.

The *frontal* or *anterior fonticulus* (fig. 356) is the largest, and is placed at the junction of the sagittal, coronal, and frontal sutures; it is lozenge-shaped, and measures about 4 cm. in its anteroposterior and 2.5 cm. in its transverse diameter. The *occipital* or *posterior fonticulus* (fig. 356) is triangular in form and is situated at the junction of the sagittal and lambdoidal sutures.

The *sphenoidal* and *mastoid fonticuli* (fig. 357) are small, irregular in shape, and correspond respectively with the sphenoidal and mastoid angles of the parietal bones. An additional fonticulus is sometimes seen in the sagittal suture at the region of the obelion.

The fonticuli are usually closed by the growth and extension of the bones which surround them, but sometimes they are the sites of separate ossific centres which develop into sutural bones. The occipital and sphenoidal fonticuli are obliterated within two or three months after birth; the mastoid fonticulus is usually closed about the end of the first year, and the frontal, about the middle of the second year.

The smallness of the face at birth is mainly accounted for by the rudimentary condition of the maxillæ and mandible, the non-eruption of the teeth, and the small size of the maxillary air-sinuses and nasal cavities. At birth the nasal cavities lie almost entirely between the orbits, and the lower border of the anterior nasal aperture is only a little below the level of the orbital floor. With the eruption of the deciduous teeth there is an enlargement of the face and jaws, and these changes are still more marked after the second dentition.

The skull grows rapidly from birth to the seventh year, by which time the lamina cribrosa of the ethmoidal bone, the foramen magnum, and the petrous parts of the temporal bones have reached their full size, and the orbital cavities are only a little smaller than those of the adult. Growth is slow from the seventh year

FIG. 357.—Skull at birth, showing sphenoidal and mastoid fonticuli.

until the approach of puberty, when a second period of activity occurs : this results in an increase in all directions, but it is especially marked in the frontal and facial regions, where it is associated with the development of the air-sinuses.

Obliteration of the sutures of the vault of the skull takes place as age advances. It may commence between the ages of thirty and forty on the inner surface, and about ten years later on the outer surface of the skull ; the dates given are, however, only approximate, as it is impossible to state with anything like accuracy the time at which the sutures are closed. Obliteration usually occurs first in the lower part of the coronal suture, next in the posterior part of the sagittal, and then in the lambdoidal.

In old age the skull generally becomes thinner and lighter, but in a small proportion of cases it increases in thickness and weight. The most striking feature of the old skull is the diminution in the size of the maxillæ and mandible consequent on the loss of the teeth and the absorption of the alveolar processes. This is associated with a marked reduction in the vertical measurement of the face and with an alteration in the angles of the mandible.

SEX DIFFERENCES IN THE SKULL.

Until the age of puberty there is little difference between the skull of the female and that of the male. The skull of an adult female is as a rule lighter and smaller, and its capacity about 10 per cent. less, than that of the male. Its walls are thinner and its muscular ridges less strongly marked ; the glabella, superciliary arches, and mastoid processes are less prominent and the corresponding air-sinuses are small or rudimentary. The upper margin of the orbit is sharp, the forehead vertical,

the frontal and parietal tuberosities prominent, and the vault somewhat flattened. The contour of the face is more rounded, the facial bones are smoother, and the maxillæ and mandible and their contained teeth smaller. From what has been said it will be seen that more of the infantile characteristics are retained in the skull of the adult female than in that of the adult male. A well-marked male or female skull can easily be recognised as such, but in some cases the respective characteristics are so indistinct that the determination of the sex may be difficult or impossible.

FIG. 358.—Outline of side view of skull.

CRANIOLOGY

Skulls vary in size and shape, and the term craniology is applied to the study of these variations.

The capacity of the cranial cavity constitutes a good index of the size of the brain which it contained, and is most conveniently arrived at by filling the cavity with shot and measuring the contents in a graduated vessel. Skulls may be classified according to their capacities as follows:

1. *Microcephalic*, with a capacity of less than 1350 c.cm.—e.g. those of native Australians and Andaman Islanders.
2. *Mesocephalic*, with a capacity of from 1350 c.cm. to 1450 c.cm.—e.g. those of African negroes and Chinese.
3. *Megacephalic*, with a capacity of over 1450 c.cm.—e.g. those of Europeans, Japanese and Eskimos.

In comparing the shape of one skull with that of another it is necessary to adopt some definite position in which the skulls should be placed during the process of examination. They should be so placed that a line carried through the lower margin of the orbit and upper margin of the opening of the external acoustic meatus is in the horizontal plane. The normæ of one skull can then be compared with those of another, and the differences in contour and surface-form noted. Further, it is necessary that the various linear measurements used to determine the shape of the skull should be made between definite and easily localised points on its surface. The principal points may be divided into two groups: (1) those in the median plane, and (2) those on either side of it (fig. 358).

The points in the median plane are the:

Mental point. The most prominent point of the chin.

Alveolar point or prosthion. The central point of the anterior margin of the upper alveolar arch.

Akanthion. The tip of the anterior nasal spine.

Subnasal point. The middle of the lower border of the anterior nasal aperture, at the base of the anterior nasal spine.

Rhinion. The most prominent point of the internasal suture.

Nasion. The central point of the frontonasal suture.

Glabella. The point in the middle line at the level of the superciliary arches.

Ophryon. The point in the middle line of the forehead at the level where the temporal lines most nearly approach each other.

Bregma. The meeting point of the coronal and sagittal sutures.

Obelion. A point in the sagittal suture on a level with the parietal foramina.

Lambda. The point of junction of the sagittal and lambdoidal sutures.

Occipital point. The point in the middle line of the occipital bone farthest from the glabella.

Inion. The external occipital protuberance.

Opisthion. The mid-point of the posterior margin of the foramen magnum.

Basion. The mid-point of the anterior margin of the foramen magnum.

The points on either side of the median plane are the :

Gonion. The outer margin of the angle of the mandible.

Jugal point. The angle between the temporal border of the zygomatic bone and the upper border of the zygomatic arch.

Dacryon. The point of union of the anterosuperior angle of the lacrimal with the frontal bone and the frontal process of the maxilla.

Pterion. The point where the great wing of the sphenoidal bone joins the sphenoidal angle of the parietal.

Stephanion. The point where the temporal line intersects the coronal suture.

Auricular point. The centre of the orifice of the external acoustic meatus.

Supra-auricular point. A point on the posterior root of the zygoma, above the middle of the orifice of the external acoustic meatus.

Asterion. The point of meeting of the lambdoidal, masto-occipital, and mastoparietal sutures.

The *horizontal circumference* of the cranium is measured in a plane passing through the glabella in front, and the occipital point behind. It averages about 50 cm. in the female and 52.5 cm. in the male.

The *occipitofrontal* or *longitudinal arc* is measured from the basion over the middle line of the vertex to the opisthion, while the *basinasal length* is the distance between the basion and the nasion. These two measurements, plus the antero-posterior diameter of the foramen magnum, represent the *vertical circumference* of the cranium.

The *length* is measured from the glabella to the occipital point, while the *breadth* or greatest transverse diameter is usually found a little above and behind the opening of the external acoustic meatus. The proportion of breadth to length $\frac{\text{breadth} \times 100}{\text{length}}$ is termed the *cephalic index* or *index of breadth*.

The *height* is measured from the basion to the bregma, and the proportion of height to length $\frac{\text{height} \times 100}{\text{length}}$ constitutes the *vertical* or *height index*.

In studying the face the principal points to be noticed are the proportion of its length to its breadth, the shape of the orbits and of the anterior nasal aperture, and the degree of projection of the jaws.

The *length of the face* is measured from the nasion to the chin, or, if the mandible be wanting, to the alveolar point; its *width* is the distance between the zygomatic arches. By comparing the length with the width of the face, skulls may be divided into two groups; *dolichofacial* (long-faced) and *brachyfacial* (short-faced).

The *orbital index* signifies the proportion which the orbital height bears to the orbital width, thus :

$$\frac{\text{orbital height} \times 100}{\text{orbital width}}$$

The *nasal index* expresses the proportion which the width of the anterior nasal aperture bears to the height of the nose, the latter being measured from the nasion to the lower margin of the nasal aperture, thus :

$$\frac{\text{nasal width} \times 100}{\text{nasal height}}$$

The degree of projection of the jaws is determined by the *gnathic* or *alveolar index*, which represents the proportion between the basi-alveolar and basinasal lengths, thus :

$$\frac{\text{basi-alveolar length} \times 100}{\text{basinasal length}}$$

The *dental index* is arrived at by comparing the *dental length* (i.e. the distance between the anterior surface of the first premolar and the posterior surface of the third molar tooth of the maxilla) with the basinasal length, thus :

$$\frac{\text{dental length} \times 100}{\text{basinasal length}}$$

The following table, modified from that given by Duckworth,* illustrates how some of these indices may be utilised in the classification of skulls :

INDEX.	CLASSIFICATION.	NOMENCLATURE.	EXAMPLES.
1. Cephalic .	Below 75	Dolichocephalic	Kaffirs and Native Australians
	Between 75 and 80 .	Mesaticephalic .	Europeans and Chinese
	Above 80	Brachycephalic .	Mongolians and Andamans
2. Orbital .	Below 84	Microseme . . .	Tasmanians and Native Australians
	Between 84 and 89 .	Mesoseme . . .	Europeans .
	Above 89	Megaseme . . .	Chinese and Polynesians
3. Nasal . .	Below 48	Leptorhine . . .	Europeans
	Between 48 and 53 .	Mesorhine . . .	Japanese and Chinese
	Above 53	Platyrrhine . . .	Negroes and Native Australians
4. Gnathic .	Below 98	Orthognathous .	Europeans
	Between 98 and 103 .	Mesognathous .	Chinese and Japanese
	Above 103	Prognathous . .	Native Australians

Applied Anatomy.—Occasionally a protrusion of the brain or its membranes may take place through one of the sutures, owing to non-closure. When the protrusion consists of membranes only, and is filled with cerebrospinal fluid, it is called a *meningocele*; when it consists of brain as well as membranes, it is termed an *encephalocele*. These malformations are usually found in the middle line, and most frequently at the back of the head, the protrusion taking place between the centres of ossification of the occipital squama (see p. 196). They generally occur through the upper part of the vertical fissure, which is the last to close, but not uncommonly through the lower part, when the foramen magnum may be incomplete. More rarely these protrusions are met with in other situations, as in the sagittal, lambdoidal, and other sutures, or through abnormal gaps at the sides or base of the skull.

The chief function of the skull is to protect the brain, and therefore those portions of the skull which are most exposed to external violence are thicker than those which are shielded from injury by overlying muscles. Thus, the skull-cap is thick and dense, whereas the temporal squamæ, being protected by the Temporales muscles, and the inferior occipital fossæ, being shielded by the muscles at the back of the neck, are thin and fragile. Fracture of the skull is further prevented by its elasticity, its rounded shape, and its construction of a number of secondary elastic arches, each made up of a single bone. The manner in which vibrations are transmitted through the bones of the skull is also of importance as regards its protective mechanism, at all events as far as the base is concerned. In the vault, the bones being of a fairly equal thickness and density, vibrations are transmitted in a uniform manner in all directions, but in the base owing to the varying thickness and density of the bones, this is not so; and therefore in this situation there are special buttresses which serve to carry the vibrations in certain definite directions. At the front of the skull, on either side, is the ridge which separates the anterior from the middle fossa of the base; and behind, the ridge or buttress which separates the middle from the posterior fossa; and if any violence is applied to the vault, the vibrations would be carried along these buttresses to the sella turcica, where they meet. This part has been termed the 'centre of resistance,' and here there is a special protective mechanism to guard the brain. The subarachnoid cavity at the base of the brain is dilated, and the cerebrospinal fluid which fills it acts as a water-cushion to shield the brain from injury. In like manner, when violence is applied to the base of the skull, as in falls upon the feet, the vibrations are carried backwards through the occipital crest, and forwards through the basilar part of the occipital and body of the sphenoid to the vault of the skull.

* W. L. H. Duckworth, *Morphology and Anthropology*, Cambridge University Press.

Fractures of the skull are best considered as affecting either the vault or the base. Fractures of the vault generally involve the whole thickness of the bone; but sometimes the inner table alone is fractured, and portions of it driven inwards. As a rule, in fracture of the skull, the inner table is more splintered and comminuted than the outer, and this is due to several causes. It is thinner and more brittle; the force of the violence as it passes inwards becomes broken up, and is more diffused by the time it reaches the inner table; the bone being in the form of an arch bends as a whole and spreads out, and thus presses the particles together on the convex surface of the arch, i.e. the outer table, and forces them asunder on the concave surface or inner table; and, lastly, there is nothing firm under the inner table to support it and oppose the force. Fractures of the vault may be either simple, or starred and comminuted, and the fragments may be depressed or elevated. Cases of fracture with elevation of the fractured portion are uncommon, and can only be produced by direct wound. In comminuted fracture, a portion of the skull is broken into several pieces, the lines of fracture radiating from a centre where the chief impact of the blow was felt; if the fracture is also depressed, a fissure circumscribes the radiating lines, enclosing a portion of the skull. If this area is circular it is termed a 'pond' fracture, and has probably been caused by a round instrument, as a life-preserver or hammer; if elliptical in shape it is termed a 'gutter' fracture, and owes its shape to the instrument which has produced it, as a poker. Fracture of the outer table alone may occur in the region of the frontal air-sinuses where the two tables are completely separated.

Fractures of the base of the skull may be produced by *indirect* or *direct* violence.

I. In cases of the former class the violence is applied to the vertex or some part of the cranial convexity, as when a person falls from a height on to his head and a fracture of the base results. The mechanism of this form of fracture was formerly explained by the doctrine of *contrecoup*, i.e. that the force was transmitted from one side of the skull to the other; but this view is no longer held, and there are at the present day two theories as to the mode of causation of these fractures. (a) According to Arakeli's theory of *irradiation* all fractures of the base are produced by a fissure, which starts from the point of injury and radiates to the base. There can be little doubt that many cases of fracture of the base, especially of the middle fossæ, are caused in this way, but it is insufficient to explain all, since instances have been met with of fracture of the base of the skull in which there has been no fracture of the vault. (b) To explain these cases, another theory, known as the *compression* or *bursting* theory, has been suggested. If a hollow, elastic sphere is compressed from above downwards, it will bulge laterally, and, if the compression is sufficient, it will eventually burst in the situation where it bulges. Now, the skull is an elastic sphere, and when compression is applied to it, its diameter will be reduced along the line of greatest pressure and will therefore be increased in other directions, and may increase to such an extent that bursting occurs. In a hollow elastic sphere of uniform thickness, the bulging and subsequent bursting take place at the equatorial line midway between the two points of compression; but the skull is not of uniform thickness, and therefore the bulging and subsequent bursting take place at the weakest part.

II. Direct violence may be applied to the base of the skull in several different ways: by the impact of the vertebral column against the condyles of the occipital bone, in falls on the buttocks or feet; by the condyle of the mandible being driven against the mandibular fossa, in blows or falls on the chin; by the thrusting of a pointed instrument through the orbit or nose; by gunshot wounds through the mouth; and by a fall or a stab on the back of the head.

In the majority of cases the fracture is compound. The most common place for fracture of the base to occur is through the middle fossa, and here the fissure usually takes a fairly definite course. Starting from the point struck, which is generally somewhere in the neighbourhood of the parietal eminence, it runs downwards through the parietal and the temporal squama and across the petrous portion, frequently traversing and implicating the internal acoustic meatus, to the foramen lacerum. From this it may pass across the body of the sphenoid, through the sella turcica, to the foramen lacerum of the other side, and may indeed travel round the whole cranium so as completely to separate the anterior from the posterior part. The course of the fracture explains the symptoms to which fracture in this region may give rise: thus if the fissure pass across the internal acoustic meatus injury to the facial and acoustic nerves may result, with consequent facial paralysis and deafness; or the tubular prolongation of the arachnoid around these nerves in the meatus may be torn and thus permit of the escape of the cerebrospinal fluid should there be a communication between the internal ear and the tympanic cavity together with rupture of the tympanic membrane, as is frequently the case; again, if the fissure pass across the sella turcica and the mucoperiosteum covering the under surface of the body of the sphenoid is torn, blood will find its way into the pharynx and be swallowed, and after a time vomiting of blood will result. Fractures of the anterior fossa, involving the bones forming the roof of the orbit and nasal cavity, are generally the result of blows on the forehead; but fracture of the lamina cribrosa of the ethmoid may be a complication of fracture of the nasal bone. When the fracture implicates the roof of the orbit, the blood finds its way into this cavity, and, travelling forwards, appears as a subconjunctival ecchymosis. If the roof of the nasal cavity be fractured, the blood escapes from the nose.

In rare cases there may be also escape of cerebrospinal fluid from the nose should the dura mater and arachnoid have been torn. In fractures of the posterior fossa, extravasation of blood may appear at the nape of the neck, beneath the muscles attached to the superior nuchal line of the occipital bone.

Deformities of the skull.—Local deformities of the skull are not rare in syphilis, taking the form of gummas which not infrequently break down and suppurate, and of periosteal thickenings which are known as *Parrot's nodes* when they occur around the coronal and sagittal sutures in infants. General enlargement of the skull, producing characteristic deformities of various types, occurs in certain rare diseases such as otitis deformans, acromegaly, and leontiasis ossea; it also is present in the much commoner disorders, rickets and hydrocephalus. In rickety cases the skull becomes enlarged from the formation of periosteal outgrowths of soft tissue on the outer side of the skull. These deposits are very rich in blood-vessels, and occur between the ridges of the cranial bones and their centres of ossification, and are symmetrically arranged—often about the anterior fontanelle. The anterior fontanelle itself, instead of closing between the 18th and 24th months, as it normally does, remains patent in rickets until the third or even the sixth year. The general shape of the skull alters. The forehead is high and square, with prominent frontal eminences, and the head tends to be cubical or box-shaped: the enlargement of the head in rickets appears to be greater than it really is because the development of the facial bones is retarded. The base of the nose may appear sunken, from retarded development of the basis cranii. In marked cases of rickets these changes in the shape of the skull are permanent. In congenital hydrocephalus, or enlargement of the head due to the presence of excess of fluid in the ventricles of the brain, the cranium becomes globular, and its bones are thin and often widely separated.

The tympanic antrum, situated in the mastoid portion of the temporal bone, is often the seat of suppuration as a result of infection extending backwards from the tympanic cavity. In such cases, the surgeon has to open the antrum in order to give exit to the pus; this he does by introducing his gouge in the supramental triangle (see p. 203). A line is drawn horizontally through the upper border of the bony external acoustic meatus, and a second vertically through the posterior wall of the meatus, and the gouge is applied in the angle where these two lines intersect; if the instrument be introduced at a higher level it will open the middle fossa of the skull. It is to be carried in the direction of the external acoustic meatus—inwards, forwards, and a little upwards—for a distance of from 1 to 1.5 cm., when the antrum will be reached. In some cases of middle-ear trouble, septic thrombosis of the transverse sinus takes place, and it becomes necessary to work backwards and explore the sinus.

In connexion with the bones of the face a common malformation is *cleft palate*. The cleft usually starts posteriorly, and its most elementary form is a bifid uvula; or the cleft may extend through the soft palate; or the posterior part of the whole of the hard palate may be involved, the cleft extending as far forwards as the incisive foramen. In the

FIG. 359.—The premaxilla and its sutures (after Albrecht).

severest forms, the cleft extends through the alveolus and passes between the incisive or premaxillary bone and the rest of the maxilla; that is to say, between the lateral incisor and canine teeth. In some instances, the cleft runs between the central and lateral incisor teeth: and this has induced some anatomists to believe that the premaxillary bone is developed from two centres (fig. 359) and not from one, as was stated on p. 229. The medial segment, bearing a central incisor, is called an *endognathion*; the lateral segment, bearing the lateral incisor, is called a *mesognathion*. The cleft may affect one or both

sides; if the latter, the central part is frequently displaced forwards and remains united to the septum of the nose, the deficiency being complicated with a cleft in the lip (hare-lip). On examining a cleft palate in which the alveolus is not implicated, the cleft will generally appear to be in the median line, but occasionally is unilateral and in some cases bilateral. To understand this it must be borne in mind that three processes are concerned in the formation of the palate—the palatine processes of the two maxillæ, which grow in horizontally and unite in the middle line; and the ethmiovomerine process, which grows downwards from the base of the skull and frontonasal process to unite with the palatine processes in the middle line. In those cases where the palatine processes fail to unite with each other and with the median process, the cleft of the palate is median; where one palatine process unites with the median septum, the other failing to do so, the cleft in the palate is unilateral. In some cases where the palatine processes fail to meet in the middle, the ethmiovomerine process grows downwards between them and thus produces a bilateral cleft. Occasionally there may be a hole in the middle line of the hard palate, the anterior part of the hard and the soft palate being perfect; this is rare, because, as a rule, the union of the various processes progresses from before backwards, and therefore the posterior part of the palate is more frequently defective than the anterior.

The bones of the face are sometimes fractured as the result of direct violence. Those most commonly broken are the nasal bones and the mandible; the latter is by far the most frequently fractured of all the facial bones. Fracture of the *nasal bone* is for the most part transverse, and takes place about 1.25 cm. from the free margin. The broken portion may be displaced backwards or more generally to one side by the force which produced the lesion. The *zygomatic bone* is probably never broken alone—that is to say, without fracture of some of the other bones of the face. The *zygomatic arch* is occasionally fractured, and when this occurs as a result of direct violence the fragments may be displaced inwards. Fractures of the *maxilla* may vary much in degree, from the chipping off of a portion of the alveolar arch to an extensive comminution of the whole bone from severe violence, as the kick of a horse. The most common situation for a fracture of the *mandible* is in the neighbourhood of the canine tooth, as at this spot the bone is weakened by the deep socket for the root of this tooth; it is next most frequently fractured at the angle; then at the symphysis; and finally the neck of the condyle or the coronoid process may be broken. Occasionally a double fracture may occur, one in either half of the bone. The fractures are usually compound, from laceration of the mucous membrane covering the gums. Displacement readily occurs and is difficult to rectify: it results in inequality in the line of the teeth and is commonly due to the muscles attached in the region of the symphysis dragging this portion downwards.

Necrosis of dental origin, or as the result of syphilis, is of frequent occurrence in the maxilla or the mandible: it may also occur as the result of fumes of phosphorus in persons engaged in the manufacture of matches. In the maxilla cysts occur in the antrum. In either jaw they occur in connexion with the teeth, those associated with unerupted teeth being called *dentigerous cysts*, and those in connexion with the stumps of diseased teeth, *dental cysts*. Tumours, innocent or malignant, originate in either jaw. The results of distention of the walls of the maxillary antrum by fluid or growth are given on p. 227.

In the operation of excision of the maxilla, the central incisor tooth having been extracted, the incision is begun just below the medial canthus of the eye and passes along the side of the nose round the ala and down the middle line of the upper lip into the mouth. A second incision is made from the commencement of the first along the lower border of the orbit as far as the prominence of the zygomatic bone. The flap thus formed is reflected, so as to expose the bone. The periosteum attached along the lower margin of the orbit is now to be incised, and the periosteum covering the floor of the orbit is raised from the bone, for in all cases it is essential that this mucous layer should not be removed. The mouth is now widely opened with a gag, and the mucous membrane covering the hard palate incised down to the bone in the middle line, and the soft palate separated from the hard. The surgeon having first separated the ala of the nose from its bony attachment, proceeds to divide the connexions of the bone with the other bones of the face. They are (1) the junction with the zygomatic bone, the line of section being carried into the inferior orbital fissure; (2) the frontal process of the maxilla; a small portion of its upper extremity, connected with the nasal bone in front, the lacrimal bone behind, and the frontal bone above, being left; (3) the connexion with the opposite maxilla and with the palatine, are broken through. The bone is now firmly grasped and the remaining attachments of the orbital plate with the ethmoid, and of the back of the bone with the palatine, are broken through. Occasionally, in removing the maxilla, it will be found that the orbital plate can be saved, and this should always be done if possible. A horizontal saw-cut should then be made just below the intraorbital foramen.

THE EXTREMITIES

The extremities or limbs are four in number: a *superior pair*, subservient mainly to prehension; and an *inferior pair*, intended for support and locomotion. Both pairs are constructed after a common type, but certain functional differences are observed between them.

The bones by which the upper and lower limbs are attached to the trunk constitute respectively the shoulder and pelvic girdles. The *shoulder girdle* or *girdle of the superior extremities* is formed by the scapulæ and clavicles, and is imperfect in front and behind. In front, however, it is completed by the upper end of the sternum, with which the medial ends of the clavicles articulate. Behind, it is widely imperfect, the scapulæ being connected to the trunk by muscles only. The *pelvic girdle* or *girdle of the inferior extremities* is formed by the hip-bones which articulate with each other in front at the symphysis pubis. It is imperfect behind, but the gap is filled by the upper part of the sacrum. The pelvic girdle, with the sacrum, is a complete ring, massive and comparatively rigid, in marked contrast to the lightness and mobility of the shoulder girdle.

BONES OF THE SUPERIOR EXTREMITY

THE SCAPULA

The **scapula** or shoulder-blade is a flat, triangular bone, with two surfaces, three borders, and three angles.

FIG. 360.—Left scapula. Costal surface.

The *costal surface* (fig. 360) presents a broad cavity, the *subscapular fossa*. The medial two-thirds of the fossa are marked by several oblique ridges, which run lateralwards and upwards. The ridges give attachment to the tendinous intersections, and the surfaces between them to the fleshy fibres, of the *Subscapularis*; the lateral third of the fossa is covered by this muscle. The fossa is separated from the vertebral border by smooth triangular areas at the medial and inferior angles of the bone, and in the interval between the angles by a narrow ridge; these triangular areas and the intervening ridge

afford attachment to the *Serratus anterior*. At the upper part of the fossa the bone is bent on itself along a line corresponding with the attached margin of the spine.

The *dorsal surface* (fig. 361) is arched from above downwards, and is subdivided into two fossæ by a projecting plate of bone, the *spine*; the portion

FIG. 361.—Left scapula. Dorsal surface.

above the spine is called the *supraspinatus fossa*, and that below it the *infraspinatus fossa*. The *supraspinatus fossa* is concave and smooth; its medial two-thirds give origin to the *Supraspinatus*. The *infraspinatus fossa* is much larger than the preceding; towards its vertebral margin a shallow concavity is present at its upper part; the central part is convex, while that near the axillary border is deeply grooved. From the medial two-thirds of the fossa the *Infraspinatus* takes origin; the lateral third is covered by this muscle.

From the lower part of the glenoid cavity an elevated ridge runs downwards and backwards to the vertebral border, about 2.5 cm. above the inferior angle; it gives attachment to a fibrous septum which separates the Infraspinatus from the Teres major and Teres minor. The upper part of the surface between the ridge and the axillary border is narrow; it gives origin to the Teres minor, and is crossed by a groove for the passage of the scapular circumflex vessels. The lower part is somewhat triangular; it gives origin to the Teres major, and over it the *Latissimus dorsi* glides; frequently the latter muscle takes origin by a few fibres from this part of the bone. The two parts are separated by an oblique line which runs downwards and backwards from the axillary border; a fibrous septum is attached to this oblique line, and separates the Teres muscles from each other.

The *spine* is a triangular plate of bone, which crosses obliquely the medial four-fifths of the dorsal surface of the scapula at its upper part, and separates the supra- from the infraspinatus fossa. It begins at the vertebral border by a smooth, triangular area over which the tendon of insertion of the lower part of the *Trapezius* glides, and, gradually becoming more elevated, ends in the acromion, which overhangs the shoulder-joint. It is flattened from above downwards, and its apex is directed towards the vertebral border. It has two surfaces and three borders. Its *superior surface* forms a part of the supraspinatus fossa, and gives origin to a portion of the Supraspinatus. Its *inferior surface* forms part of the infraspinatus fossa, gives origin to a portion of the Infraspinatus, and presents near its centre the orifice of a nutrient canal. The *anterior border* is attached to the dorsal surface of the bone. The *posterior border*, or *crest of the spine*, is broad, with two lips and an intervening rough surface. The *Trapezius* is attached to the lateral three-fourths of the superior lip, and a rough tubercle is generally seen on the medial portion of the crest for the tendon of insertion of the lower part of this muscle; the *Deltoides* is attached to the whole length of the inferior lip; the area between the lips is subcutaneous and partly covered by the tendinous fibres of these muscles. The *lateral border* or *base*, the shortest of the three, is thick and slightly concave; it is continuous above with the under surface of the acromion, below with the posterior surface of the neck of the scapula. It forms the medial boundary of the *great scapular notch*, which connects the supra- and infraspinatus fossæ.

The *acromion* is a large triangular or oblong process which projects at first lateralwards from the spine, and then curves forwards and upwards, so as to overhang the glenoid cavity. Its *superior surface*, directed upwards, and slightly backwards and lateralwards, is subcutaneous. Its *inferior surface* is smooth and concave. Its *lateral border* is thick and irregular, and presents three or four tubercles for the tendinous origins of the *Deltoides*. Its *medial border*, shorter than the lateral, is concave, gives attachment to a portion of the *Trapezius*, and presents near its anterior extremity a small, oval surface for articulation with the acromial end of the clavicle. Its *apex*, which corresponds to the point of meeting of the lateral and medial borders in front, is thin, and to it the *coraco-acromial ligament* is attached.

Of the three borders of the scapula, the *superior* is the shortest and thinnest; it is concave, and extends from the medial angle to the base of the coracoid process. At its lateral part is the *scapular notch*, formed partly by the base of the coracoid process. This notch is converted into a foramen by the *superior transverse scapular ligament*, and transmits the *suprascapular nerve*; sometimes the ligament is ossified. From the adjacent part of the superior border the *Omohyoideus* takes origin. The *axillary border* (fig. 362) is the thickest; it begins above at the lower margin of the glenoid cavity, and runs downwards and backwards to the inferior angle. Immediately below the glenoid cavity is a rough impression, the *infraglenoid tuberosity*, about 2.5 cm. in length, which gives origin to the long head of the *Triceps brachii*; in front of this a longitudinal groove extends as far as the lower third of this border, and affords origin to part of the *Subscapularis*. The inferior third is thin and serves for the attachment of a few fibres of the Teres major behind, and of the *Subscapularis* in front. The *vertebral border* is the longest and extends from the medial to the inferior angle; it is bent so that the portion above the spine forms an obtuse angle with the part below. It gives insertion to the *Llevator*

scapulæ above the triangular surface at the apex of the spine, to the Rhomboideus minor on the edge of that surface, and to the Rhomboideus major below it; the last muscle is usually attached by means of a fibrous arch, connected above to the lower part of the triangular surface at the apex of the spine, and below to the lower part of the border.

Of the three angles, the *medial*, at the junction of the superior and vertebral borders, is thin, smooth, and rounded; it gives attachment to a few fibres of the Levator scapulæ. The *inferior angle*, thick and rough, is formed by the union of the vertebral and axillary borders; its dorsal surface gives origin to the Teres major and frequently to a few fibres of the Latissimus dorsi. The *lateral angle* is the thickest part of the bone, and is sometimes called the *head of the scapula*. On it is a shallow pyriform, articular surface, the *glenoid cavity* (fig. 362), which looks lateralwards and forwards and articulates with the head of the humerus; it is broader below than above and its vertical diameter is the longer. To its margin is attached a fibrocartilaginous lip, the *glenoidal labrum*, which deepens the cavity. At its apex is a small elevation, the *supraglenoid tuberosity*, to which the long head of the Biceps brachii is attached.

The *neck* of the scapula (collum scapulæ) is the somewhat constricted part of the bone which immediately surrounds the glenoid cavity, and separates it superiorly from the base of the coracoid process; it is more distinctly marked below and behind than above and in front.

The *coracoid process* is a thick curved process attached by a broad base to the upper part of the head of the scapula; it runs at first upwards, forwards, and medialwards; then, becoming smaller, it changes its direction, and projects forwards and lateralwards. The ascending portion is flattened from before backwards, and presents in front a smooth concave surface, across which the Subscapularis passes. The horizontal portion is flattened from above downwards; its upper surface is convex and irregular, and gives attachment to the Pectoralis minor; its under surface is smooth; its medial and lateral borders are rough—the former gives attachment to the Pectoralis minor and the latter to the coraco-acromial ligament; the apex is embraced by the conjoined tendon of origin of the Coracobrachialis and short head of the Biceps.

FIG. 362.—Left scapula. Lateral view.

brachii, and gives attachment to the coracoclavicular fascia. On the medial part of the root of the coracoid process is a rough impression for the attachment of the conoid ligament; and running from it obliquely forwards and lateralwards, on to the upper surface of the horizontal portion, is an elevated ridge for the attachment of the trapezoid ligament.

FIG. 363.—Plan of ossification of the scapula. From seven centres.

Structure.—The head, processes, and thickened parts of the bone contain spongy substance; the rest consists of a thin layer of compact bone. The central part of the supraspinatous fossa and the greater part of the infraspinatous fossa are thin; occasionally the bone is found wanting in these situations, and the adjacent muscles are separated only by fibrous tissue.

Ossification (fig. 363).—The scapula is ossified from seven or more centres: one for the body, two for the coracoid process, two for the acromion, one for the vertebral border, and one for the inferior angle.

Ossification of the body begins in the eighth week of foetal life, and the centre spreads to form an irregular quadrilateral plate of bone, immediately behind the glenoid cavity. This plate extends so as to form the chief part of the bone, the spine growing up from its dorsal surface about the third month. At birth, the glenoid cavity, coracoid process, acromion, vertebral border, and inferior angle are cartilaginous. In the first year of life, ossification begins in the middle of the coracoid process, and this process joins the rest of the bone about the fifteenth year. Between the fourteenth and twentieth years, ossification of the remaining parts usually takes place in the following order; first, in the root of the coracoid process; secondly, near the base of the acromion; thirdly, in the inferior angle and contiguous part of the vertebral border; fourthly, near the extremity of the acromion; fifthly, in the vertebral border. The base of the acromion is formed by an extension from the spine; the two separate centres of the acromion unite, and then join with the extension from the spine. The upper third of the glenoid cavity is ossified from a subcoracoid centre, which appears between the tenth and eleventh and joins between the sixteenth and the eighteenth years. Further, an

epiphysial plate appears for the lower part of the glenoid cavity, while the tip of the coracoid process frequently presents a separate centre. These various epiphyses are joined to the bone by the twenty-fifth year. Failure of bony union between the acromion and spine sometimes occurs, the junction of these two parts being then effected by fibrous tissue, or by an imperfect articulation.

Applied Anatomy.—Fractures of the body of the scapula are rare, owing to the mobility of the bone, the thick layers of muscles by which it is encased, and the elasticity of the ribs on which it rests. Fracture of the neck is also uncommon. The most frequent course of a fracture is from the scapular notch to the infraglenoid tuberosity, and it derives its principal interest from its simulation of a subglenoid dislocation of the humerus. The diagnosis can be made by noting the alteration in the position of the coracoid process. The acromion is more frequently broken than any other part of the bone, and fibrous union is very liable to follow.

The presence of 'winged scapulae' (*scapulae alatae*) described in thin persons of feeble muscular development in whom the lower angles of the scapulae project unduly, is due partly to abnormal roundness of the thoracic wall ('barrel-shaped chest,' p. 192), and partly to weakness and flaccidity of the *Latissimus dorsi* and *Serratus anterior*. The shoulders are held low in these subjects, and the clavicles slope downwards and forwards, carrying with them the scapulae, which fit ill to the posterior wall of the chest and so tend to project from it.

Tumours of various kinds grow from the scapula. Of the innocent form probably the osteomata are the most common. When an osteoma grows from the costal surface of the scapula, as it sometimes does, it is of the compact variety, such as usually grows from membrane-formed bones, as the bones of the skull. Sarcomatous tumours sometimes grow from the scapula, and may necessitate removal of the bone, with or without amputation of the upper limb. The bone may be excised by a T-shaped incision, and the flaps being reflected, the removal is commenced from the vertebral border, so that the subscapular vessels which lie along the axillary border are among the last structures divided, and can be readily secured.

THE CLAVICLE (CLAVICULA)

The clavicle or collar-bone (figs. 364 and 365) articulates medially with the manubrium sterni, and laterally with the acromion of the scapula.* It is a long bone, and is placed nearly horizontally at the upper and anterior part of the thorax. It is curved somewhat like the italic letter *f*, presenting a double curvature, with a convexity forwards at the sternal end and a concavity forwards at the acromial end. Its lateral third is flattened, whilst its medial two-thirds are of a rounded or prismatic form.

The lateral third has two surfaces, an upper and a lower; and two borders, an anterior and a posterior. The *upper surface* is flat and rough: it affords attachment to the *Deltoides* in front, and the *Trapezius* behind: between these a small portion of the bone is subcutaneous. The *under surface* is flat; at its posterior border, near the junction of the prismatic and flattened portions of the bone, is a rough eminence, the *coracoid tuberosity* (conoid tubercle); this overlies the coracoid process of the scapula, and gives attachment to the *conoid ligament*. From this tuberosity, the *oblique* or *trapezoid ridge* runs forwards and lateralwards, and affords attachment to the *trapezoid ligament*. The *anterior border* is concave, thin, and rough, and gives origin to a portion of the *Deltoides*; at its medial part there is frequently a tubercle, the *deltoid tubercle*. The *posterior border*, convex, rough, and thicker than the anterior, gives insertion to a part of the *Trapezius*.

The medial two-thirds constitute the prismatic portion of the bone, which is marked by three borders, separating three surfaces. The *anterior border* is continuous with the anterior border of the flat portion. Its lateral part is smooth, and corresponds to the interval between the attachments of the *Pectoralis major* and *Deltoides*; its medial part forms the lower boundary of an elliptical surface for the attachment of the clavicular portion of the *Pectoralis major*. The *superior border* is continuous with the posterior border of the flat portion, and separates the anterior from the posterior surface. Smooth and

* The clavicle acts especially as a fulcrum to enable the muscles to give lateral motion to the arm. It is accordingly absent in those animals whose fore-limbs are used only for progression, but is present for the most part in animals whose anterior extremities are clawed and used for prehension, though in some of them—as, for instance, in a large number of the carnivora—it is merely a rudimentary bone suspended among the muscles, and not articulating with either the scapula or sternum.

rounded laterally, it becomes rough towards the medial third for the attachment of the Sternocleidomastoideus, and ends at the upper angle of the sternal extremity. The *subclavian* or *posterior border* separates the posterior from the inferior surface, and extends from the coracoid tuberosity to the costal tuberosity; it forms the posterior boundary of the groove for the Subclavius, and gives attachment to a layer of cervical fascia which envelops the Omohyoideus. The *anterior surface* is between the superior and anterior borders. Its lateral part looks upwards, and is continuous with the superior surface of the flattened portion; it is smooth, convex, and nearly subcutaneous, being covered only by the Platysma. Its medial part is divided by a narrow subcutaneous region into two areas; a lower, elliptical in form, and directed forwards, for the attachment of the Pectoralis major; and an upper, for the attachment of the Sternocleidomastoideus. The *posterior or cervical surface* is smooth,

FIG. 364.—Left clavicle. Superior surface.

FIG. 365.—Left clavicle. Inferior surface.

and looks backwards towards the root of the neck. It is limited, above, by the superior border; below, by the subclavian border; medially, by the margin of the sternal extremity; and laterally, by the coracoid tuberosity. It is in relation with the transverse scapular vessels, and, at the junction of the curves of the bone, with the brachial plexus of nerves and the subclavian vessels. Near the sternal extremity, it gives attachment to part of the Sternohyoideus; and near its middle is a foramen directed lateralwards, which transmits a nutrient artery into the bone. A second nutrient foramen may be present on this, or on the inferior, surface. The *inferior or subclavian surface* is between the anterior and subclavian borders. It is narrow medially, but gradually increases in width laterally, and is continuous with the under surface of the flat portion. On its medial part is a rough area, the *costal tuberosity* (rhomboid impression), rather more than 2 cm. in length, for the attachment of the costoclavicular ligament. The rest of this surface is grooved, and gives insertion to the Subclavius muscle; the coracoclavicular fascia splits to enclose the muscle and is attached to the margins of the groove.

The *sternal extremity* of the clavicle is triangular in form, directed medialwards, and a little downwards and forwards; it presents an articular facet, concave from before backwards, convex from above downwards, which

articulates with the articular disc of the sternoclavicular joint. The lower part of the facet is continued on to the inferior surface of the bone as a small semi-oval area for articulation with the cartilage of the first rib. The circumference of the articular surface is rough for the attachment of ligaments; the upper angle and a narrow rough area below it give attachment to the articular disc.

The acromial extremity presents a small, flattened, oval surface directed slightly downwards, for articulation with the acromion of the scapula. The upper margin of the facet is rough for the attachment of the acromioclavicular ligament.

In the female, the clavicle is generally shorter, thinner, less curved, and smoother than in the male.* In the male the acromial end is on a level with, or slightly higher than, the sternal end; in the female the acromial end is a little below the level of the sternal end. In persons who perform considerable manual labour the clavicle becomes thicker and more curved, and its ridges for muscular attachment more prominently marked.

Structure.—The clavicle consists of spongy substance, enveloped by a layer of compact bone, which is much thicker in the intermediate part than at the extremities of the bone.

Ossification.—The clavicle begins to ossify before any other bone in the body: it is ossified from (a) two primary centres, a medial and a lateral, for the body,† which appear during the fifth or sixth week of foetal life and fuse about the forty-fifth day; and (b) a secondary centre for the sternal end, which appears about the eighteenth or twentieth year, and unites with the body of the bone about the twenty-fifth year.

In a 14 mm. embryo the future clavicle is represented by a band of connective tissue which extends from the acromion of the scapula to the tip of the first rib and is continuous with the rudiment of the sternum. In this band a medial and a lateral mass of 'precartilage' is developed, and in the adjacent ends of these masses the two centres for the body of the bone appear and soon fuse with each other. The sternal and acromial ends of the precartilaginous masses are converted into cartilage and into this the ossification of the body of the bone extends.

Applied Anatomy.—The clavicle is very frequently fractured, since it is much exposed to violence, and is the only bony connexion between the upper limb and the trunk, acting as a buttress to keep the point of the shoulder away from the thorax. It is, moreover, slender, and is very superficial. It may be broken by direct or indirect violence. The most common cause is, however, indirect violence, as the result of force applied to the hand or shoulder, and the bone then gives way at the junction of its lateral with its intermediate third, that is to say, at the junction of the two curves, for this is its weakest part. The fracture is generally oblique, and the displacement of the lateral fragment is downwards, forwards, and medialwards. The deformity is mainly due to the weight of the arm acting upon the fragment when the buttress-like action of the bone is gone, assisted by the muscles which pass from the thorax to the upper extremity. The medial fragment, as a rule, is little displaced. The main vessels of the upper limb and the great nerve-cords of the brachial plexus lie beneath the bone on the first rib and are liable to be wounded, especially in fracture from direct violence, when the force of the blow drives the broken ends inwards. Fortunately the Subclavius intervenes between these structures and the clavicle, and often protects them from injury.

The clavicle is occasionally the seat of sarcomatous tumours, rendering the operation of excision of the entire bone necessary. This is an operation of considerable difficulty and danger. It is best performed by exposing the bone freely, disarticulating at the acromial end, and turning it forwards. The removal of the lateral part is comparatively easy, but resection of the medial part is fraught with difficulty, the main danger being the risk of wounding the great veins which are in relation with its deep surface.

Great deformity of the clavicle may be met with in rickets, the natural curvatures of the bone being exaggerated until it takes an S shape, and 'green-stick' fracture is not uncommonly seen associated therewith.

* F. G. Parsons (*Journal of Anatomy and Physiology*, vol. li.) gives 153 mm. as the average length of the male clavicle, and 138 mm. as the average length of the female clavicle.

† Mall, *American Journal of Anatomy*, vol. v., 1900; Fawcett, *Journal of Anatomy and Physiology*, vol. xiv.

THE HUMERUS

The humerus (figs. 367 and 368), the longest and largest bone of the upper limb, is divisible into a body and two extremities.

The **upper extremity** consists of a large rounded *head* joined to the body by a constricted portion called the *neck*, and two eminences, the *greater* and *lesser tubercles*.

The **head** (fig. 366), nearly hemispherical in form, is directed upwards, medialwards, and a little backwards, it articulates with the glenoid cavity of the scapula. The circumference of its articular surface is slightly constricted, and is termed the *anatomical neck*, in contradistinction to a constriction below the tubercles called the *surgical neck* which is frequently the seat of fracture.

FIG. 366.—Head of left humerus, from above.

The *anatomical neck* forms an obtuse angle with the body and is best marked in the lower half of its circumference; in the upper half it is represented by a narrow groove separating the head from the tubercles. It affords attachment to the articular capsule of the shoulder-joint, and is perforated by numerous foramina for the transmission of blood-vessels.

The **greater tubercle** is situated laterally to the head and lesser tubercle. Its upper surface is convex and marked by three impressions; the highest of these gives insertion to the *Supraspinatus*; the middle, to the *Infraspinatus*; the lowest one, and the bone for about 2.5 cm. below it, to the *Teres minor*. The lateral surface of the greater tubercle is convex, rough, and continuous with the lateral surface of the body.

The **lesser tubercle**, more prominent than the greater, is situated in front, and is directed forwards and medialwards. On its upper and front part is an impression for the insertion of the tendon of the *Subscapularis*.

The tubercles are separated from each other by the *intertubercular sulcus* (bicipital groove), which lodges the long tendon of the *Biceps brachii*, transmits a branch of the anterior humeral circumflex artery to the shoulder-joint, and gives insertion to the tendon of the *Latissimus dorsi*. The sulcus diminishes in depth as it descends, and, near the junction of the upper with the middle third of the bone, is continuous with the anteromedial surface. The lips of the sulcus are called, respectively, the *crests of the greater and lesser tubercles* (bicipital ridges), and form the upper parts of the anterior and medial borders of the body of the bone.

The **body** or shaft, almost cylindrical above, but prismatic and flattened below, has three borders and three surfaces.

The **anterior border** runs from the front of the greater tubercle to the coronoid fossa, and separates the anteromedial from the anterolateral surface. Its upper part, the crest of the greater tubercle, serves for the insertion of the tendon

FIG. 367.—Left humerus. Anterior view.

FIG. 368.—Left humerus.
Posterior view.

of the *Pectoralis major*. Its middle part forms the anterior boundary of the *deltoid tuberosity*; its lower part is smooth and rounded, and affords attachment to the *Brachialis*.

The *lateral border* runs from the back of the greater tubercle to the lateral epicondyle, and separates the antero-lateral from the posterior surface. Its upper half, rounded and indistinctly marked, gives insertion to the lower part of the *Teres minor*, and origin to the lateral head of the *Triceps brachii*; its middle part is traversed by a shallow oblique depression, the *sulcus nervi radialis* (musculospiral groove). Its lower part forms a prominent rough margin, the *lateral supracondylar ridge*, which is curved forwards, and gives attachment to the lateral intermuscular septum. The proximal two-thirds of this ridge give origin to the *Brachioradialis*; the distal third, to the *Extensor carpi radialis longus*.

The *medial border* extends from the lesser tubercle to the medial epicondyle and separates the anteromedial from the posterior surface. Its upper part, the crest of the lesser tubercle, gives insertion to the tendon of the *Teres major*. About the middle is a slight impression for the insertion of the *Coracobrachialis*, and just below this is the *nutrient canal*, directed downwards; sometimes there is a second nutrient canal at the commencement of the radial sulcus. The inferior third forms the *medial supracondylar ridge* which gives attachment to the medial intermuscular septum, and is prominent below.

The *anterolateral surface* is directed lateralwards above, where it is smooth, rounded, and covered by the *Deltoides*; forwards and lateralwards below, where it is slightly concave from above downwards, and gives origin to part of the *Brachialis*. About the middle of this surface is a rough elevation, triangular in shape with the apex below, the *deltoid tuberosity* for the insertion of the *Deltoides*; below this is the *sulcus nervi radialis*, which is directed from behind, forwards, and downwards, and transmits the *radial nerve* and *arteria profunda brachii*.

The *anteromedial surface*, less extensive than the anterolateral, is directed forwards above, forwards and medialwards below; its upper part, which is narrow, forms the floor of the *intertubercular sulcus* and gives insertion to the tendon of the *Latissimus dorsi*; its middle part is slightly rough for the attachment of some of the fibres of the tendon of insertion of the *Coracobrachialis*. Its

lower part is smooth, concave from above downwards, and gives origin to the *Brachialis*.*

The *posterior surface* appears somewhat twisted, so that its upper part is directed a little medialwards, its lower part backwards. Nearly the whole of this surface is covered by the lateral and medial heads of the *Triceps brachii*, the former arising above, the latter below the radial sulcus.

The lower extremity (fig. 369) is flattened from before backwards, and curved slightly forwards; it ends in a broad, articular surface which is divided into two parts by a smooth ridge. Projecting on either side, at a higher level than the articular surface, are the lateral and medial epicondyles. The *articular surface* is curved slightly forwards, and its medial extremity is lower than the lateral. The lateral portion of this surface is a smooth, rounded eminence, named the *capitulum* of the humerus; it articulates with the cup-shaped depression on the head of the radius, and is limited to the front and lower part of the bone. On the medial side of the capitulum is a shallow groove, in which the medial margin of the head of the radius is received; above the front part of the capitulum is a small depression, the *radial fossa*, which receives the anterior border of the head of the radius, when the forearm is flexed. The

FIG. 369.—Lower extremity of left humerus, from below.

medial portion of the articular surface is named the *trochlea* or pulley; it articulates with the semilunar notch of the ulna. Its central part consists of a deep groove which winds spirally from before backwards and lateralwards round the lower end of the bone; the groove is deeper behind where it expands to occupy the whole width of the trochlea. The medial margin is prominent, and forms about two-thirds of a circle, and the adjacent portion of the articular surface is convex on the front and lower part of the bone; on the posterior surface the convexity disappears. The lateral margin is rounded in front and below, where it is separated from the capitulum by a groove which receives the margin of the head of the radius; posteriorly the lateral margin of the trochlea is sharp and prominent. Above the front of the trochlea is a depression, the *coronoid fossa*, which receives the coronoid process of the ulna when the forearm is flexed, and above the back of it is a deep triangular depression, the *olecranon fossa*, in which the summit of the olecranon is received when the forearm is extended. These fossae are separated from one another by a thin lamina of bone, which is sometimes perforated by the *supratrochlear foramen*; they are lined in the recent state by the synovial stratum, and their margins

* A hook-shaped process of bone, the *supracondylar process*, varying from 2 mm. to 20 mm. in length, is not infrequently found projecting from the anteromedial surface of the body of the humerus 5 cm. above the medial epicondyle. It is curved downwards and forwards, and its pointed end is connected to the medial border, just above the epicondyle, by a fibrous band which gives origin to a portion of the *Pronator teres*; through the arch completed by this fibrous band the median nerve and brachial artery pass, when these structures deviate from their usual course. Sometimes the nerve alone is transmitted through it, or the nerve may be accompanied by the ulnar artery, in cases of high division of the brachial. A well-marked groove is usually found behind the process, in which the nerve and artery are lodged. This arch is the homologue of the supracondylar foramen found in many animals, and probably serves in them to protect the nerve and artery from compression during the contraction of the muscles in this region.

afford attachment to the fibrous stratum of the articular capsule of the elbow-joint. The *lateral epicondyle* is small and tuberculated, and curved a little forwards; it gives attachment to the radial collateral ligament of the elbow-joint and to a tendon common to the origin of the Supinator and some of the extensor muscles of the forearm. The *medial epicondyle*, larger and more prominent than the lateral, is directed a little backwards; it gives attachment to the ulnar collateral ligament of the elbow-joint, to the Pronator teres, and to a common tendon of origin of some of the flexor muscles of the forearm; the ulnar nerve and posterior ulnar recurrent artery run in a groove (*sulcus nervi ulnaris*) on the back of this epicondyle. The epicondyles are continuous above with the supracondylar ridges.

Structure.—The extremities consist of spongy substance, covered with a thin layer of compact bone (fig. 370); the body is composed of a cylinder of compact bone, thicker at the centre than towards the extremities, and contains a large medullary canal which extends along its whole length.

FIG. 370.—Longitudinal section of head of left humerus.

Epiphysial line

Ossification (figs. 371, 372). — The humerus is ossified from eight centres, one for each of the following parts: the body, the head, the greater tubercle, the lesser tubercle, the capitulum and lateral part of the trochlea, the medial part of the trochlea, and one for each epicondyle. The centre for the body appears near the middle of the bone in the eighth week of foetal life, and gradually extends towards the extremities, which at birth are cartilaginous. During the first year, occasionally before birth, ossification begins in the head of the bone, during the third year in the greater tubercle, and during the fifth in the lesser tubercle. By the sixth year the centres for the head and tubercles have joined to form a single large epiphysis, which fuses with the body about the twentieth year. The lower end of the humerus is ossified as follows. At the end of the second year ossification begins in the capitulum and extends medial-

wards to form the chief part of the articular surface; the centre for the medial part of the trochlea appears about the twelfth year. Ossification begins in the medial epicondyle about the fifth year, and in the lateral about the thirteenth or fourteenth year. The centre for the lateral epicondyle fuses with those for the trochlea and capitulum and the epiphysis thus formed unites with the body about the sixteenth or seventeenth year; the medial epicondyle unites with the body about the eighteenth year.

Applied Anatomy.—The upper end of the humerus, though the first to ossify, is the last to join the body, and the length of the bone is mainly due to growth from the upper epiphysial plate. Hence, in cases of amputation through the arm in young subjects, the humerus continues to grow considerably, and the lower end of the bone, which immediately after the operation was covered with a thick cushion of soft tissue, begins to project, thinning the soft parts and rendering the stump conical. This may necessitate the removal of about 5 cm. of the bone, and even after this operation a recurrence of the conical stump may take place. The region of the upper epiphysis is a common site for the growth of tumours, both innocent and malignant.

Fractures of the humerus are common. The bone may be broken by direct or indirect violence, like the other long bones; but, in addition to this, it is probably more frequently fractured by muscular action than any other bone of this class, it is usually the body of the bone, just below the insertion of the Deltoides, which is thus broken, and the accident has been known to happen from throwing a stone. Fractures of the upper end may take place either through the anatomical or surgical neck, or a separation of the greater tubercle may occur. Fracture of the anatomical neck is a very rare accident; in fact, it is doubted by some whether it ever occurs. Fracture of the surgical neck of the bone is not uncommon, and impaction may occur; on the other hand, the upper end of the lower segment may be displaced into the axilla and may damage the vessels or nerves.

The fracture somewhat closely simulates dislocation of the shoulder-joint, but can be distinguished by the fact that the head of the bone remains in its normal position and the great tubercle still forms the most prominent point of the shoulder. Separation of the upper epiphysis sometimes occurs in the young subject, and is marked by a characteristic deformity, consisting in the presence of an abrupt projection at the front of the joint a short distance below the coracoid process, caused by the upper end of the diaphysis. In fractures of the body of the humerus the lesion may take place at any point, but appears

FIG. 371.—Plan of ossification of the humerus.

FIG. 372.—Epiphysial lines of humerus in a young adult. Anterior aspect.

The lines of attachment of the articular capsules are in blue.

to be more common in the lower than the upper part of the bone. The points of interest in connexion with these fractures are: (1) that the radial nerve may be injured as it lies in the groove on the bone, or may become involved in the callus which is subsequently thrown out; and (2) the frequency of non-union, which is believed to be more common in the humerus than in any other bone. In fractures of the lower end it is important to distinguish between those that involve the elbow-joint and those that do not; the former are always serious, as they may lead to impairment of the utility of the limb; they include the T-shaped fracture and oblique fractures which involve the articular surface. Those which do not involve the joint are the transverse fracture above the epicondyles, and the so-called epitrochlear fracture, where the tip of the medial epicondyle is broken off, generally by direct violence.

THE RADIUS

The radius (figs. 373 and 374) is situated on the lateral side of the forearm. Its upper end is small, and forms only a small part of the elbow-joint; its lower end is large, and forms a large part of the wrist-joint. It is a long bone, prismatic in form and slightly curved longitudinally.

The upper extremity consists of a head, neck, and tuberosity. The head is of a cylindrical form, and on its upper surface is a shallow cup or fovea for articulation with the capitulum of the humerus. The circumference of the head is smooth; it is broad medially where it articulates with the radial notch

FIG. 373.—Bones of left forearm. Volar aspect.

Fig. 374.—Bones of left forearm. Dorsal aspect.

of the *ulna*, narrow in the rest of its extent, which is embraced by the *annular ligament*. The head is supported on a round, smooth, and constricted *neck*. Below the medial part of the neck is an eminence, the *radial tuberosity*; its surface is divided into a posterior rough portion for the insertion of the tendon of the *Biceps brachii*, and an anterior smooth portion on which a *bursa* is interposed between the tendon and the bone.

The *body* or *shaft* is prismoid in form, narrower above than below, and slightly curved, so as to be convex laterally. It has three borders and three surfaces.

The *volar* or *anterior border* separates the volar from the lateral surface, and extends from the lower part of the tuberosity above, to the anterior part of the base of the styloid process below. Its upper part is prominent, and from its oblique direction has received the name of the *oblique line*; it gives origin to the *Flexor digitorum sublimis* and *Flexor pollicis longus*; the surface above the line gives insertion to part of the *Supinator*. The middle part of the volar border is indistinct and rounded. The lower part is prominent, and gives insertion to the *Pronator quadratus*, and attachment to the *dorsal carpal ligament*; it ends in a small tubercle, into which the tendon of the *Brachioradialis* is inserted.

The *dorsal* or *posterior border* separates the dorsal from the lateral surface; it is well-marked only in the middle third of the bone.

The *interosseous crest* or *medial border* separates the volar from the dorsal surface, and gives attachment to the antibrachial interosseous membrane (fig. 378); it begins above, at the back part of the tuberosity, and its upper part is rounded and indistinct. It becomes sharp and prominent as it descends, and at its lower part divides into two ridges which are continued to the anterior and posterior margins of the ulnar notch; to the posterior ridge the lower part of the antibrachial interosseous membrane is attached while the triangular surface between the ridges gives insertion to part of the *Pronator quadratus*.

The *volar* or *anterior surface* is concave in its upper three-fourths, and gives origin to the *Flexor pollicis longus*; its lower fourth is broad and flat, and affords insertion to the *Pronator quadratus*. A prominent ridge limits the insertion of the *Pronator quadratus* below, and between this and the inferior border is a triangular rough surface for the attachment of the *volar radiocarpal ligament*. At the junction of the upper with the middle third of this surface is the *nutrient canal*, directed obliquely upwards.

The *dorsal surface* is convex and smooth in the upper third of its extent, and covered by the *Supinator*. Its middle third, broad and slightly concave, gives origin to the *Abductor pollicis longus* above, and to the *Extensor pollicis brevis* below. Its lower third, broad and convex, is covered by the tendons of the muscles which subsequently run in the grooves on the lower end of the bone.

The *lateral surface* is convex; its upper third gives insertion to the *Supinator*; near its centre is a rough ridge, for the insertion of the *Pronator teres*; its lower part is covered by the tendons of the *Abductor pollicis longus* and *Extensor pollicis brevis*.

The *lower extremity* is large and is provided with two articular surfaces—one below, for the carpus, and another at the medial side, for the ulna. The carpal articular surface (fig. 379) is triangular, concave, smooth, and divided by a slight anteroposterior ridge into two parts. The lateral, triangular part, articulates with the navicular bone; the medial, quadrilateral part, with the lunate bone. The articular surface for the ulna is called the *ulnar notch* (sigmoid cavity); it is narrow, concave, smooth, and articulates with the head of the ulna. These two articular surfaces are separated by a prominent ridge, to which the base of the *triangular articular disc* is attached; this disc separates the wrist-joint from the distal radio-ulnar articulation. The lower end of the bone has three non-articular surfaces—volar, dorsal, and lateral. The *volar surface*, rough and irregular, affords attachment to the *volar radiocarpal ligament*. The *dorsal surface* is convex, affords attachment to the *dorsal radiocarpal ligament*, and is marked by three grooves. Enumerated from the lateral side, the first groove is broad, but shallow, and subdivided by a slight ridge; the lateral part transmits the tendon of the *Extensor carpi radialis longus*, the medial, the tendon of the *Extensor carpi radialis brevis*.

The second groove is deep but narrow, and bounded laterally by a sharp ridge; it runs obliquely downwards and lateralwards, and transmits the tendon of the Extensor pollicis longus. The third groove is broad, for the passage of the tendons of the Extensor indicis proprius and Extensor digitorum communis. The *lateral surface* is prolonged obliquely downwards into a strong, conical projection, the *styloid process*, the base of which gives attachment to the tendon of the Brachioradialis, the apex to the radial collateral ligament of the wrist-joint. On the lateral surface of this process is a flat groove, for the tendons of the Abductor pollicis longus and Extensor pollicis brevis.

FIG. 375.—Plan of ossification of the radius. From three centres.

FIG. 376.—Epiphysial lines of radius in a young adult. Anterior aspect.

The line of attachment of the articular capsule of the wrist-joint is in blue.

Structure.—The structure of the radius is like that of the other long bones.

Ossification (figs. 375, 376).—The radius is ossified from three centres: one for the body, and one for either end. That for the body appears near the middle of the bone, in the eighth week of foetal life. About the close of the second year, ossification begins in the lower end; and at the fifth year, in the upper end. The upper epiphysis fuses with the body at the age of seventeen or eighteen years, the lower about the age of twenty. An additional centre, sometimes found in the radial tuberosity, appears about the fourteenth or fifteenth year.

THE ULNA

The ulna (figs. 373 and 374) is placed at the medial side of the forearm, parallel with the radius. The upper extremity is thick and strong, and forms a large part of the elbow-joint; the body or shaft diminishes in size from above downwards; the lower extremity is small, and is excluded from the wrist-joint by the interposition of an articular disc:

On the upper extremity, (fig. 377) are two curved processes, the olecranon and the coronoid process; and two concave articular cavities, the semilunar and radial notches.

The olecranon is a thick, curved eminence, on the upper and posterior part of the ulna. It is bent forwards at the summit so as to present a prominent lip which is received into the olecranon fossa of the humerus when the forearm is extended. Its base is contracted where it joins the body, and is

FIG. 377.—Upper part of left ulna.
Lateral aspect.

the narrowest part of the upper end of the ulna. Its posterior surface, directed backwards, is triangular, smooth, subcutaneous, and is covered by a bursa. Its superior surface, of quadrilateral form, is marked behind by a rough impression for the insertion of the Triceps brachii, and in front, close to the margin, by a slight groove for the attachment of part of the articular capsule of the elbow-joint; between the groove for the articular capsule and the impression for the Triceps brachii is a smooth area which is separated from the tendon of the Triceps brachii by a bursa. Its anterior surface forms the upper part of the semilunar notch. On its borders are grooves continuous with that on the anterior part of the superior surface; that on the medial border gives attachment to the posterior part of the ulnar collateral ligament; that on the lateral border to part of the articular capsule. From the medial border a part of the Flexor carpi ulnaris arises; to the lateral the Anconæus is attached.

The coronoid process is a prismatic eminence projecting forwards from the front of the upper extremity of the ulna. Its base is continuous with the body of the bone, and is of considerable strength. Its apex is pointed, slightly curved upwards, and is received into the coronoid fossa of the humerus when the forearm is flexed. Its upper surface forms the lower part of the semilunar notch. Its antero-inferior surface is concave, and marked by a rough impression for the insertion of the Brachialis; this impression extends on to the upper part of the body of the bone. At the junction of this surface with the front of the body is a rough eminence, the tuberosity of the ulna, which gives insertion to a part of the Brachialis; to the lateral

border of this tuberosity the oblique cord is attached. On its lateral surface is a narrow, oblong, articular depression, the radial notch. Its medial surface ends superiorly in a prominent, free margin which gives attachment to part of the ulnar collateral ligament. At the front part of this surface is a round eminence for the origin of a small part of the Flexor digitorum sublimis; behind the eminence is a depression for part of the origin of the Flexor digitorum profundus; descending from the eminence is a ridge which gives origin to the ulnar head of the Pronator teres. Frequently a rounded muscular bundle of the Flexor pollicis longus arises by a tendinous slip from the lower part of the coronoid process.

The semilunar notch (greater sigmoid cavity), for articulation with the trochlea of the humerus, is a large depression, formed by the olecranon and the coronoid process. It is concave from above downwards and its

part is constricted and sometimes crossed by a groove; it is divided into a medial and a lateral portion by a smooth ridge running from the summit of the olecranon to the tip of the coronoid process. The medial portion is the larger, and is slightly concave transversely; the lateral is convex above, slightly concave below.

The radial notch (lesser sigmoid cavity) (fig. 377) is an oblong, articular depression on the lateral side of the coronoid process for the reception of the circumferential articular surface of the head of the radius. It is concave from before backwards, and its anterior and posterior extremities serve for the attachment of the annular ligament.

The body or shaft, at its upper part, is prismatic in form, and curved, with its convexity directed posteriorly and lateralwards; its central part is prismatic and straight; its lower part is rounded and bent a little lateralwards. The body tapers gradually from above downwards, and has three borders and three surfaces.

The *volar* or *anterior* border separates the volar from the medial surface; it begins above at the prominent medial angle of the coronoid process, and ends below in front of the styloid process. Its upper part, well defined, and its middle portion, smooth and rounded, give origin to the *Flexor digitorum profundus*; its lower fourth forms a prominent ridge for the origin of the *Pronator quadratus*.

The *dorsal* border is subcutaneous, and separates the medial from the dorsal surface; it begins above at the apex of the triangular subcutaneous surface at the back part of the olecranon, and ends below at the back of the styloid process; its upper three-fourths are well marked and give attachment to an aponeurosis which affords a common origin to the *Flexor carpi ulnaris*, the *Extensor carpi ulnaris*, and the *Flexor digitorum profundus*; its lower fourth is smooth and rounded.

The *interosseous crest* or *lateral* border separates the volar from the dorsal surface and gives attachment to the antibrachial interosseous membrane (fig. 378); it begins above by the union of two lines, which converge from the extremities of the radial notch and enclose between them a triangular area for the origin of part of the *Supinator*; it ends below at the head of the ulna. Its upper part is sharp and prominent, its lower fourth smooth and rounded.

The *volar* or *anterior* surface is broader above than below; its upper three-fourths are concave and give origin to the *Flexor digitorum profundus*; its lower fourth is covered by the *Pronator quadratus* and is separated from the remaining portion by a ridge which is directed obliquely downwards and medialwards, and marks the extent of origin of the *Pronator quadratus*. At the junction of the upper with the middle third of this surface is the nutrient canal, directed obliquely upwards.

The *dorsal* surface, directed backwards and lateralwards, is broad above; convex and somewhat narrower in the middle; narrow and rounded below. On its upper part is an oblique ridge which runs downwards from the dorsal end of the radial notch to the dorsal border; the upper part of the ridge affords attachment to the *Supinator*, and the triangular surface above it receives the insertion of the *Anconeus*. Below this ridge the dorsal surface is subdivided by a *perpendicular line*, into two parts: the medial part is smooth, and covered by the *Extensor carpi ulnaris*; the lateral gives origin from above downwards to the *Abductor pollicis longus*, the *Extensor pollicis longus*, and the *Extensor indicis proprius*.

The *medial* surface is broad and concave above, narrow and convex below. Its upper three-fourths give origin to the *Flexor digitorum profundus*; its lower fourth is subcutaneous.

Fig. 378.—Transverse section of left radius and ulna, showing attachment of interosseous membrane.

The lower extremity of the ulna is small, and has two eminences; the lateral and larger is termed the head of the ulna; the medial, narrower and more projecting, the styloid process. The head presents an articular surface, the distal part of which, of a semilunar form (fig. 379), is directed downwards, and comes into contact with the upper surface of the triangular articular disc which separates the ulna from the radiocarpal or wrist-joint; the remaining portion, directed lateralwards, is narrow and convex, and is received into the ulnar notch of the radius. The *styloid process* projects from the medial and posterior part of the bone; it descends a little lower than the head, and its rounded apex affords attachment to the ulnar collateral ligament of the wrist-joint. The head is separated from the styloid process, below by a depression for the attachment of the apex of the triangular articular disc, and behind by a shallow groove for the tendon of the Extensor carpi ulnaris.

FIG. 379.—Lower extremities of right radius and ulna, from below.

Structure.—The structure of the ulna is similar to that of the other long bones.

Ossification (figs. 380, 381).—The ulna is ossified from three centres: one each for the body, the inferior extremity, and the top of the olecranon. Ossification begins near the middle of the body, about the eighth week of foetal life, and soon extends through the greater part of the bone. About the fourth year, a centre appears in the middle of the head, and extends into the styloid process. About the tenth year, a centre appears in the olecranon near its extremity, but the chief part of this process is formed by an upward extension of the body; sometimes the extremity of the olecranon is ossified from two centres. The upper epiphysis joins the body about the sixteenth, the lower about the twentieth year.

Applied Anatomy.—The bones of the forearm are more often broken together than separately. Fractures of both bones may be produced by either direct or indirect violence, though more commonly by direct violence. When indirect force is applied to the forearm the radius as a rule gives way, though both bones may suffer. Fractures from indirect force generally take place somewhere about the middle of the bones, while those from direct violence may occur at any part, but are most frequent in the lower half of the bones. The fractures are usually transverse, but may be more or less oblique. A point of interest in connexion with these fractures is the tendency for the two bones to unite across the interosseous membrane; the limb should therefore be put up in a position midway between supination and pronation, which is not only the most comfortable position, but also separates the bones most widely from each other. Anterior and posterior splints are applied in these cases, and should be rather wider than the limb, so as to prevent any side pressure on the bones.

The special fractures of the ulna are: (1) Fracture of the olecranon, which is usually caused by direct violence, by falls on the elbow with the forearm flexed, but occasionally by muscular action in sudden contraction of the Triceps brachii; the most common site of this fracture is at the constricted portion where the olecranon joins the body of the bone, and the fracture is usually transverse; but any part may be broken, and even a thin shell may be torn off. Fractures from direct violence are occasionally comminuted. If the fibrous structures around the process are not torn the displacement is slight; otherwise the olecranon may be drawn up for a very considerable distance. (2) Fracture of the coronoid process may occur as a complication of dislocation backwards of the bones of the forearm, but it is doubtful if it ever takes place as an uncomplicated injury. (3) Fractures of the body of the ulna may occur at any part, but usually take place at or a little below the middle of the bone. They are generally the result of direct violence, but may

occur as a complication of dislocation of the radius. (4) The styloid process may be knocked off by direct violence.

Fractures of the radius may consist of: (1) Fracture of the head of the bone; this for the most part takes place in conjunction with some other lesion, but may occur as an uncomplicated injury. (2) Fracture of the neck also may occur, but is usually complicated with other injury. (3) Fractures of the body of the radius are very common, and may take place at any part of the bone. They may be caused by direct or indirect violence. In fracture of the upper third of the body—that is to say, above the insertion of the Pronator teres—the displacement is very great. The upper fragment is strongly supinated by the Biceps and Supinator, and flexed by the Biceps: while the lower fragment is pronated and drawn towards the ulna by the two Pronators. If such a fracture be put up in the ordinary position, midway between supination and pronation, the bone will unite

FIG. 381.—Epiphysial lines of ulna in a young adult. Lateral aspect.

FIG. 380.—Plan of ossification of the ulna. From three centres.

The line of attachment of the articular capsules are in blue.

with the upper fragment in a position of supination, and the lower one in the mid-position, and thus considerable impairment of the movement of supination will result; the limb should therefore be put up with the forearm supinated. (4) The most important fracture of the radius is that of the lower end (Colles's fracture). The fracture is transverse, and generally takes place about 2.5 cm. from the lower extremity. It is caused by falls on the palm of the hand, and is an injury of advanced life, occurring more frequently in the female than in the male. In consequence of the manner in which the fracture is caused, the upper fragment is driven into the lower, and impaction commonly is the result; excess of violence may, however, disimpact, the lower fragment being split into two or more pieces, so that no fixation occurs. Separation of the lower epiphysis of the radius may take place in the young. This injury and Colles's fracture may be distinguished from other injuries in this neighbourhood—especially dislocation of the wrist, with which they are liable to be confounded—by observing the relative positions of the styloid processes of the ulna and radius. In the natural condition of parts, with the arm hanging by the side, the styloid process of the radius is on a lower level than that of the ulna. After fracture or separation of the epiphysis the styloid process of the radius is on the same level as, or on a higher level than, that of the ulna, whereas it would be unaltered in position in dislocation. Reduction in the case of Colles's fracture is usually easily effected by traction on the hand, the limb being subsequently splinted with the hand deflected towards the ulnar side.

FIG. 382.—Bones of the left hand. Volar surface.

THE SKELETON OF THE HAND

The skeleton of the hand (figs. 382 and 383) consists of three segments : (1) the carpus or wrist bones ; (2) the metacarpus or bones of the palm ; and (3) the phalanges or bones of the digits.

THE CARPUS

The **carpal bones** (*ossa carpi*), eight in number, are arranged in two rows. Those of the proximal row, from the radial to the ulnar side, are named the navicular, lunate, triquetral, and pisiform bones ; those of the distal row, in the same order, are the greater multangular, lesser multangular, capitate, and hamate bones.

COMMON CHARACTERISTICS OF THE CARPAL BONES

Each bone (excepting the pisiform) presents six surfaces. Of these the *volar* or *anterior* and the *dorsal* or *posterior surfaces* are rough, for ligamentous attachment ; the *dorsal surfaces* are the broader, except in the navicular and lunate bones. The *superior* or *proximal*, and *inferior* or *distal surfaces* are articular, the superior generally convex, the inferior concave ; the *medial* and *lateral surfaces* are also articular where they are in contact with contiguous bones, otherwise they are rough and tuberculated. The structure in all is similar, viz. spongy substance enclosed in a layer of compact bone.

THE NAVICULAR BONE (*Os NAVICULARE MANUS*) 5~

The **navicular bone** (fig. 384), the largest of the proximal row, has received its name from its fancied resemblance to a boat. It is situated at the radial

FIG. 384.--The left navicular bone.

side of the carpus, its long axis being from above downwards, lateralwards, and forwards. The *superior surface* is convex, smooth, of triangular shape, and articulates with the lower end of the radius. The *inferior surface*, directed downwards and backwards, is also smooth, convex, and triangular ; it is divided by an indistinct ridge into a lateral part which articulates with the greater multangular bone, and a medial with the lesser multangular bone. On the *dorsal surface* is a narrow, rough groove which serves for the attachment of ligaments. The *volar surface* is concave above, but elevated at its lower and lateral part into a rounded *tubercle*, which is directed forwards and gives attachment to the transverse carpal ligament and sometimes to a few fibres of the *Abductor pollicis brevis*. The *lateral surface*, rough and narrow, gives attachment to the radial collateral ligament of the wrist. On the *medial surface* are two articular facets ; of these, the superior is flat and crescentic in shape, and articulates with the lunate bone ; the inferior is concave and forms with the lunate bone a concavity for the head of the capitate bone.

THE LUNATE BONE (OS LUNATUM) 34

The **lunate** or **semilunar** bone (fig. 385), distinguished by its deep concavity and crescentic outline, is situated in the centre of the proximal row of the carpus, between the navicular and triquetral bones. The *superior surface*, convex and smooth, articulates with the radius. The *inferior surface* is

FIG. 385.—The left lunate bone.

deeply concave, and of greater extent from before backwards than transversely: it articulates with the head of the capitate bone, and, by a long, narrow facet with the hamate bone. The *dorsal* and *volar* surfaces are rough, for the attachment of ligaments, the dorsal being the smaller. On the *lateral surface* is a semilunar facet for articulation with the navicular bone, and on the *medial surface* a quadrilateral facet for the triquetral bone.

THE TRIQUETRAL BONE (OS TRIQUETRUM) 35

The **triquetral** or **cuneiform** bone (fig. 386) may be distinguished by its pyramidal shape, and by an oval isolated facet for articulation with the pisiform bone. It is situated at the ulnar side of the proximal row of the carpus with its long axis from above downwards and medialwards. The *superior surface*

FIG. 386.—The left triquetral bone.

FIG. 387.—The left pisiform bone.

presents a medial rough non-articular portion, and a lateral convex smooth portion which articulates with the triangular articular disc of the wrist. The *inferior surface*, directed lateralwards, is concave, sinuously curved, and smooth for articulation with the hamate bone. The *dorsal surface* is rough for the attachment of ligaments. The *volar surface* displays, on its medial part, an oval facet for articulation with the pisiform bone; its lateral part is rough for ligamentous attachment. The *lateral surface*, or base of the pyramid, is marked by a flat, quadrilateral facet for articulation with the lunate bone. The *medial surface*, or summit of the pyramid, is pointed and gives attachment to the ulnar collateral ligament of the wrist.

THE PISIFORM BONE (OS PISIFORME) 36

The **pisiform** bone (fig. 387) is situated in front of the triquetral bone, and may be known by its small size, and by its presenting a single, oval facet for articulation with that bone. This facet is on the dorsal surface of the bone, and its long axis is directed downwards and lateralwards. The *volar surface* is rounded and rough, and gives attachment to the Flexor carpi ulnaris. The

medial surface gives attachment to the Abductor digiti quinti and the dorsal carpal ligament; the pisometacarpal ligament is attached to the lower part of this surface. On the *anterolateral surface* is an oblique line or ridge, the distal part of which gives attachment to the volar carpal ligament. The lower part of the bone projects beyond the articular surface and presents a tubercle for the attachment of the pisohamate ligament.*

THE GREATER MULTANGULAR BONE (OS MULTANGULUM MAJUS) 4

The **greater multangular bone** or **trapezium** (fig. 388) may be distinguished by a deep groove on its volar surface. It is situated at the radial side of the carpus, between the navicular and first metacarpal bones. The

FIG. 388.—The left greater multangular bone.

superior surface is directed upwards and medialwards; medially it is smooth, and articulates with the navicular bone; laterally it is rough and continuous with the lateral surface. The *inferior surface* is oval, concave from side to side, convex from before backwards, so as to form a saddle-shaped surface for articulation with the base of the first metacarpal bone. The *dorsal surface* is rough. The *volar surface* is narrow and rough. At its upper part is a deep groove, running from above downwards; it transmits the tendon of the Flexor carpi radialis, and is bounded laterally by a ridge which affords attachment to the transverse carpal ligament, and gives origin to the Opponens pollicis, Abductor pollicis brevis and Flexor pollicis brevis. The *lateral surface* is broad and rough for the attachment of ligaments. On the *medial surface* are two facets; the upper, large and concave, articulates with the lesser multangular bone; the lower, small and oval, with the base of the second metacarpal bone.

THE LESSER MULTANGULAR BONE (OS MULTANGULUM MINUS) 4

The **lesser multangular** or **trapezoid bone** (fig. 389) is the smallest bone in the distal row. It may be known by its wedge-shaped form, the thick end of the wedge constituting the dorsal, the thin end the volar surface; and

FIG. 389.—The left lesser multangular bone.

by its having four articular facets separated by sharp edges. The *superior surface*, small, quadrilateral, and slightly concave, articulates with the navicular bone. The large *inferior surface* articulates with the proximal end of the second metacarpal bone; it is convex from side to side, concave from before

* R. H. Robbins, *Journal of Anatomy and Physiology*, vol. II.

backwards. The *dorsal* and *volar surfaces* are rough for the attachment of ligaments, the former being the larger. The *lateral surface* is convex, and articulates with the greater multangular bone. The *medial surface* is concave and smooth in front, for articulation with the capitate bone; rough behind for the attachment of an interosseous ligament.

THE CAPITATE BONE (OS CAPITATUM)

The capitate bone or os magnum (fig. 390) is the largest of the carpal bones, and occupies the centre of the wrist. It presents a rounded upper portion, the head, which is received into the concavity formed by the navicular and lunate bones; a constricted portion, the neck; and below this, the body. The

FIG. 390.—The left capitate bone.

superior surface is round, smooth, and articulates with the lunate bone. The *inferior surface* is divided by two ridges into three facets, for articulation with the second, third, and fourth metacarpal bones, that for the third being the largest. The *dorsal surface* is broad and rough. The *volar surface* is narrow, projecting and rough, for the attachment of ligaments and the oblique part of the *Adductor pollicis*. The *lateral surface* articulates, by a small facet at its anterior inferior angle, with the lesser multangular bone; behind this facet is a rough depression for the attachment of an interosseous ligament. Above this is a deep, rough groove, forming part of the neck, and serving for the attachment of ligaments; it is bounded superiorly by a smooth, convex surface, for articulation with the navicular bone. The *medial surface* articulates with the hamate bone by a smooth, oblong facet, which occupies the posterior and superior parts of this surface; its anterior part is rough for the attachment of an interosseous ligament.

THE HAMATE BONE (OS HAMATUM) S-

The hamate or unciform bone (fig. 391) may be readily distinguished by its wedge-shaped form, and the hook-like process which projects from its volar

FIG. 391.—The left hamate bone.

surface. It is situated at the medial and lower angle of the carpus, with its base directed downwards, and its apex upwards and lateralwards. The *superior*

surface, the apex of the wedge, is narrow, convex, smooth, and articulates with the lunate bone. The *inferior surface* articulates with the fourth and fifth metacarpal bones, by concave facets which are separated by a slight ridge. The *dorsal surface* is triangular, and rough for ligaments. From the lower and medial part of the *volar surface* a curved, hook-like process, the *hamulus*, is directed forwards and lateralwards. This process gives attachment, by its apex, to the transverse carpal ligament and the Flexor carpi ulnaris; by its medial surface to the Flexor brevis and Opponens digiti quinti; its lateral side is grooved for the passage of the Flexor tendons into the palm of the hand. The *medial surface* articulates with the triquetral bone by an oblong, obliquely cut facet. The upper and posterior part of the *lateral surface* articulates with the capitate bone; the rest of the surface is rough for the attachment of ligaments.

THE METACARPUS

The **metacarpus** consists of five cylindrical bones which are numbered from the lateral side (ossa metacarpalia I-V); each consists of a body and two extremities.

COMMON CHARACTERISTICS OF THE METACARPAL BONES

The **body** is prismoid in form, and curved, so as to be convex longitudinally behind, concave in front. It has three surfaces: medial, lateral, and dorsal. The *medial* and *lateral surfaces* are concave, for the attachment of the Interossei, and separated from one another by a prominent anterior ridge. The *dorsal surface* presents in its distal two-thirds a smooth, triangular, flattened area which is covered, in the recent state, by the tendons of the Extensor muscles. This surface is bounded by two lines, which commence in small tubercles situated at the sides of the digital extremity, and converge and meet some distance above the centre of the bone to form a ridge which is continued to the carpal extremity. This ridge separates two sloping surfaces for the attachment of the Interossei dorsales. To the tubercles at the digital extremities are attached the collateral ligaments of the metacarpophalangeal joints.

The **base** or **carpal extremity** is of a cuboidal form, and broader behind than in front: it articulates with the carpus, and with the adjoining metacarpal bones; its *dorsal* and *volar surfaces* are rough, for the attachment of ligaments.

The **head** or **digital extremity** presents an oblong surface markedly convex from before backwards, less so transversely; it articulates with the proximal phalanx. It is broader, and extends farther upwards, on the volar than on the dorsal surface, and is longer in the anteroposterior than in the transverse diameter. On either side of the head is a deep depression, and behind this a tubercle for the attachment of the collateral ligament of the metacarpophalangeal joint. The *dorsal surface*, broad and flat, supports the Extensor tendons; the *volar surface* is grooved for the Flexor tendons, and marked on either side by an articular eminence continuous with the terminal articular surface.

CHARACTERISTICS OF THE INDIVIDUAL METACARPAL BONES 2

The **first metacarpal bone** (fig. 392) is shorter and stouter than the others, diverges to a greater degree from the carpus, and its volar surface is directed medialwards. The *body* is flattened and broad on its dorsal surface, and does not present the ridge which is found on the other metacarpal bones; its volar surface is concave from above downwards. The *Opponens pollicis* is inserted into its radial border; the lateral head of the first Interosseus dorsalis arises from its ulnar border. The *base* presents a concavoconvex surface, for articulation with the greater multangular bone; it has no facets on its sides, but on its radial side is a tubercle for the insertion of the Abductor

pollicis longus. The head is less convex than the heads of the other metacarpal bones, and is broader from side to side than from before backwards. On its volar surface are two articular eminences, of which the lateral is the larger, for the two sesamoid bones in the tendons of the *Flexor pollicis brevis*.

FIG. 392.—The first left metacarpal bone.

The second metacarpal bone (fig. 393) is the longest, and its base the largest, of the four remaining bones. Its base is prolonged upwards and medialwards, forming a prominent ridge. It presents four articular facets: three on the upper surface and one on the lateral side. Of the facets on the upper surface the intermediate is the largest and is concave from side to side, convex from before backwards for articulation with the lesser multangular bone; the lateral is small, flat and oval for articulation with the greater multangular bone; the medial, on the summit of the ridge, is long and narrow for articulation with the capitate bone. The facet on the medial side articulates with the third metacarpal bone. The *Extensor carpi radialis longus* is inserted on the lateral part of the dorsal surface, and the *Flexor carpi radialis* on the volar surface, of the base.

The third metacarpal bone (fig. 394) is a little smaller than the second. The dorsal part of its base presents on its radial side a pyramidal eminence, the *styloid process*, which extends upwards behind the capitate bone; immediately distal to this is a rough surface for the attachment of the *Extensor carpi*

FIG. 393.—The second left metacarpal bone.

FIG. 394.—The third left metacarpal bone.

radialis brevis. The carpal articular facet is concave behind, flat in front, and articulates with the capitate bone. On the radial side is a smooth, concave facet for articulation with the second metacarpal bone, and on the ulnar side two small oval facets for the fourth metacarpal bone.

The fourth metacarpal bone (fig. 395) is shorter than the third. Its base is small and quadrilateral; on its superior surface are two facets, a large medial one for articulation with the hamate bone, and a small one at the posterolateral

angle for the capitate bone. On the lateral side are two oval facets, for articulation with the third metacarpal bone; and on the medial side, a single concave facet, for the fifth metacarpal bone.

3 The fifth metacarpal bone (fig. 396) has two facets on its *base*; that on its superior surface is saddle-shaped, and articulates with the hamate bone; that on the lateral side articulates with the fourth metacarpal bone. On its medial side is a tubercle for the insertion of the tendon of the Extensor carpi ulnaris. The dorsal surface of the body is divided by an oblique ridge, which

FIG. 395.—The fourth left metacarpal bone.

FIG. 396.—The fifth left metacarpal bone.

extends from near the ulnar side of the base to the radial side of the head. The lateral part of this surface serves for the attachment of the fourth Interosseus dorsalis; the medial part is smooth, triangular, and covered by the extensor tendons of the little finger.

THE PHALANXES (PHALANXES DIGITORUM MANUS)

The phalanges are fourteen in number, three for each finger, and two for the thumb. Each consists of a body and two extremities. The *body* tapers from above downwards, and its posterior surface is convex; its anterior surface is concave from above downwards, and flat from side to side; its sides are marked by rough ridges, which give attachment to the fibrous sheaths of the Flexor tendons. The *proximal extremities* of the bones of the first row present oval, concave articular surfaces, broader from side to side than from before backwards. On the *proximal extremity* of each of the bones of the second and third rows are two concavities separated by a median ridge. The *distal extremities* are smaller than the proximal, and each ends in two condyles separated by a shallow groove; the articular surface extends farther on the volar than on the dorsal surface, a condition best marked in the bones of the first row.

The *ungual phalanges* are convex on their dorsal, and flat on their volar surfaces; they are recognised by their small size, and by a roughened, elevated surface of a horseshoe form on the volar surface of the distal extremity of each which serves to support the sensitive pulp of the finger.

OSSIFICATION OF THE BONES OF THE HAND

The carpal bones are each ossified from a single centre, and ossification proceeds in the following order (fig. 397): in the capitate and hamate bones, during the first year, the former preceding the latter; in the triquetral bone, during the third year; in the lunate and greater multangular bones, during the fifth year, the former

preceding the latter ; in the navicular bone, during the sixth year ; in the lesser multangular bone, during the eighth year ; and in the pisiform bone, about the twelfth year.

Occasionally an additional bone, the *os centrale*, is found on the back of the carpus, lying between the navicular, lesser multangular, and capitate bones. During the second month of foetal life it is represented by a small cartilaginous nodule, which usually fuses with the cartilaginous navicular. Sometimes the styloid process of the third metacarpal bone is detached and forms an additional ossicle.

The **metacarpal bones** are each ossified from two centres ; one for the body and one for the head or distal end of each of the second, third, fourth and fifth bones ;

FIG. 397.—Plan of ossification of the bones of the hand.

CARPUS

One for head

PHALANGES
Two centres for each bone :
One for body
One for proximal extremity

one for the body and one for the base or proximal end of the first.* The first metacarpal bone is therefore ossified in the same manner as the phalanges, and this has led some anatomists to regard the thumb as being made up of three phalanges, and not of a metacarpal bone and two phalanges. Ossification begins in the middle of the body about the eighth or ninth week of foetal life, the centres for the second and third metacarpals being the first, and that for the first metacarpal the last, to appear ; about the third year the distal extremities of the metacarpals of the fingers, and the base of the metacarpal of the thumb, begin to ossify ; they unite with the bodies about the twentieth year.

The **phalanges** are each ossified from two centres ; one for the body, and one for the proximal extremity. Ossification begins in the body, about the eighth week of foetal life. Ossification of the proximal extremity commences in the bones of

* Allen Thomson (*Journal of Anatomy and Physiology*, vol. iii. 1869) pointed out that the first metacarpal bone is often developed from three centres ; that is to say, there is a separate centre for the distal end, forming a distinct epiphysis visible at the age of seven or eight years. He also stated that there are traces of a proximal epiphysis in the second metacarpal bone.

the first row between the third and fourth years, and a year later in those of the second and third rows. The two centres become united in each row between the eighteenth and twentieth years.

In the ungual phalanges the centres for the bodies appear at the distal extremities of the phalanges, instead of at the middle of the bodies, as in the other phalanges. Moreover, of all the bones of the hand, the ungual phalanges are the first to ossify.

Applied Anatomy.—The carpal bones are little liable to fracture except from extreme violence, when the parts are so comminuted as to necessitate amputation. Occasionally they are the seat of tuberculous disease. The metacarpal bones and the phalanges are sometimes broken from direct violence. There are two diseases of the metacarpal bones and phalanges which require special mention on account of their frequent occurrence. One is tuberculous dactylitis, consisting in a deposit of tuberculous material in the medullary canal, expansion of the bone, with subsequent caseation and necrosis. The other is chondroma, which is perhaps more commonly found in connexion with the metacarpal bones and phalanges than with any other bones. The tumours are usually multiple, and spring from beneath the periosteum about the epiphysal plate.

BONES OF THE INFERIOR EXTREMITY

THE HIP-BONE (OS COXÆ)

The **hip-bone** (os innominatum) (figs. 398, 399) is a large, flattened, irregularly shaped bone, constricted in the centre and expanded above and below. It articulates in front with the bone of the opposite side, and the two bones form the anterior and lateral walls of the pelvis. It consists of three parts, the ilium, ischium, and os pubis, which are distinct from each other in the young subject, but are fused in the adult; the union of the three parts takes place in and around a large cup-shaped articular cavity, the acetabulum, which is situated near the middle of the outer surface of the bone. The *ilium*, so called because it supports the flank, is the broad and expanded portion which extends upwards from the acetabulum. The *ischium* is the lowest and strongest portion of the bone; it proceeds downwards from the acetabulum, expands into a large tuberosity, and then curves forwards below a large aperture, the obturator foramen. The *os pubis* extends medialwards and downwards from the acetabulum and articulates in the middle line with the bone of the opposite side.

The *ilium* (os ilii) is divisible into two parts, the body and the ala; the separation is indicated on the internal surface by a curved line, the *arcuate line*, and on the external surface by the upper part of the margin of the acetabulum.

The **body** forms rather less than two-fifths of the acetabulum. Its *external surface* is partly articular, partly non-articular; the articular segment forms part of the lunate surface of the acetabulum, the non-articular portion contributes to the acetabular fossa. The *internal surface* of the body is part of the wall of the lesser pelvis; it gives origin to some fibres of the *Obturator internus* and is continuous below with the pelvic surfaces of the ischium and os pubis.

The **ala**, the large expanded portion, bounds the greater pelvis laterally. It has an external and an internal surface, a crest, and an anterior and a posterior border. The *external surface*, or *dorsum ilii* (fig. 398), is directed backwards and lateralwards behind, and lateralwards and downwards in front. It is smooth, convex in front, concave behind, and is bounded above by the crest, below by the upper border of the acetabulum, and in front and behind by the anterior and posterior borders. This surface is crossed by the posterior, anterior, and inferior gluteal lines. The *posterior gluteal line* (superior curved line), the shortest of the three, begins at the crest, about 5 cm. in front of its posterior extremity; it is distinctly marked above, but as it descends to the upper part of the greater sciatic notch, where it ends, it becomes less distinct, and is often lost. Behind this line is a narrow, semilunar surface, the upper part of which is rough and gives origin to a portion of the *Gluteus maximus*; the lower part is smooth, and has no muscular fibres attached to it. The *anterior gluteal*

line (middle curved line), the longest of the three, begins at the crest, about 4 cm. behind its anterior extremity, and, taking a curved direction backwards and downwards, ends at the upper part of the greater sciatic notch. A nutrient foramen is often seen near the middle of this line. The surface between the crest and the anterior and posterior glutæal lines, gives origin to the Glutæus

FIG. 398.—Right hip-bone. External surface.

medius. The *inferior glutæal line* (inferior curved line), the least distinct, begins in front at the notch on the anterior border, and, curving backwards and downwards, ends near the middle of the greater sciatic notch; the Glutæus minimus takes origin between the anterior and inferior glutæal lines. From a rough, shallow groove immediately above the acetabulum, the reflected tendon of the Rectus femoris arises.

The *internal surface* (fig. 399) of the ala is bounded above by the crest; below by the arcuate line; in front and behind by the anterior and posterior borders. Its anterior part, smooth and concave, is termed the iliac fossa;

it gives origin to the *Iliacus*, and its posterior part is perforated by a nutrient canal; the tendon of the *Psoas minor* is inserted into the arcuate line. Behind the iliac fossa is a rough surface, divided into two portions, a superior and an inferior. The inferior portion or *auricular surface*, so called from its resemblance in shape to the auricula, is coated with cartilage in the recent state, and articulates with a similar surface on the side of the sacrum. The superior

FIG. 399.—Right hip-bone. Internal surface.

portion, known as the *iliac tuberosity*, is elevated and rough, for the attachment of the posterior sacro-iliac ligaments; it is continuous above and behind with the inner lip of the iliac crest, and here it gives origin to the *Sacrospinalis* and *Multifidus* muscles. Below and in front of the auricular surface is the *pre-auricular sulcus*, more commonly present and better marked in the female than in the male; the pelvic portion of the anterior sacro-iliac ligament is attached to this sulcus.

The crest of the ilium is convex in its general outline but is sinuously curved, being concave inwards in front, and outwards behind. It is thinner at the

centre than at the extremities, and ends in the anterior and posterior superior iliac spines. The surface of the crest is divided into external and internal lips, and an intermediate line; about 5 cm. behind the anterior superior iliac spine there is a prominent tubercle on the external lip. To the external lip are attached, from before backwards, the *Tensor fasciæ latæ*, *Obliquus externus abdominis*, and *Latissimus dorsi*, and along its whole length the *fascia lata*; to the intermediate line the *Obliquus internus abdominis*; to the internal lip, the *fascia iliaca*, the *Transversus abdominis*, *Quadratus lumborum*, *Sacrospinalis*, and *Iliacus*.

The anterior border of the ala is concave and presents two projections, separated by a notch. The upper projection, at the junction of the crest and anterior border, is called the *anterior superior iliac spine*; its outer border gives attachment to the *fascia lata* and the *Tensor fasciæ latæ*; its inner border, to the *Iliacus*; its extremity affords attachment to the *inguinal ligament*, and origin to the *Sartorius*. Beneath this spine is a notch from which the *Sartorius* takes origin and across which the *lateral femoral cutaneous nerve* passes. Below the notch is the *anterior inferior iliac spine*, which ends inferiorly in the upper lip of the acetabulum; it gives attachment to the straight tendon of the *Rectus femoris* and to the *iliofemoral ligament* of the hip-joint. Medial to the anterior inferior spine is a broad, shallow groove, over which the *Iliacus* descends into the thigh. This groove is bounded medially by the *iliopectineal eminence*, which marks the union of the ilium and the os pubis.

The posterior border of the ala, shorter than the anterior, also presents two projections, the *posterior superior* and *posterior inferior iliac spines*, separated by a notch. The former serves for the attachment of the long posterior sacro-iliac ligament and the *Multifidus* muscle; the latter corresponds with the posterior end of the auricular surface. Below the posterior inferior spine is a deep notch, the *greater sciatic notch*.

The ischium (os ischii) forms the lower and posterior part of the hip-bone. It is divisible into a body and a superior and an inferior ramus.

The body enters into and constitutes a little more than two-fifths of the acetabulum. Its *external surface* forms part of the lunate surface of the acetabulum and a portion of the acetabular fossa. Its *internal surface* is part of the wall of the lesser pelvis, and gives origin to some fibres of the *Obturator internus*. Its *posterior surface* is convex, and covered by the *Piriformis* muscle. Its *antero-inferior border* is thin, and forms part of the boundary of the obturator foramen; it ends above at the acetabular notch, where it frequently presents a small tubercle, the *posterior obturator tubercle*. Its *lateral border* forms the posterior part of the rim of the acetabulum; from its *posterior border* a pointed triangular eminence, the *ischial spine*, extends backwards and medialwards. The external surface of this spine gives attachment to the *Gemellus superior*; its internal surface to the *Coccygeus*, *Levator ani*, and the *pelvic fascia*; its pointed extremity to the *sacrospinous ligament*. Above the spine is the *greater sciatic notch*, converted into a foramen by the *sacrospinous ligament*; this foramen transmits from the pelvis the *Piriformis muscle*, the superior and inferior gluteal vessels and nerves, the sciatic and posterior femoral cutaneous nerves, the internal pudendal vessels and pudendal nerve, and the nerves to the *Obturator internus* and *Quadratus femoris*. Of these, the superior gluteal vessels and nerve emerge above the *Piriformis*, the other structures below it. Below the spine is the *lesser sciatic notch*; it is converted into a foramen by the *sacrospinous* and *sacrospinous ligaments*, and transmits the tendon of the *Obturator internus*, the nerve which supplies that muscle, and the internal pudendal vessels and pudendal nerve.

The superior ramus projects downwards and backwards from the body and has three surfaces: external, internal, and posterior. The *external surface* is quadrilateral in shape. It is bounded above by a groove which lodges the tendon of the *Obturator externus*; below, it is continuous with the external surface of the inferior ramus; in front, it is limited by the posterior margin of the obturator foramen; behind, a prominent margin separates it from the posterior surface. In front of this margin the external surface gives origin to the *Quadratus femoris*, and to some of the fibres of the *Obturator externus*; its lower part gives origin to part of the *Adductor magnus*. The *internal surface* forms part of the bony wall of the lesser pelvis. In front it is limited

by the posterior margin of the obturator foramen. Below and behind, it is bounded by a sharp ridge which gives attachment to the *falciform process* of the sacrotuberous ligament; more anteriorly it gives origin to the *Transversus perinæi superficialis* and *Ischiocavernosus*.

Posteriorly the superior ramus forms a large swelling, the *tuberosity of the ischium*, which is divided into two portions: a lower, rough, somewhat triangular part, and an upper, smooth, quadrilateral portion. The lower portion is subdivided by a prominent longitudinal ridge into two parts; the lateral gives attachment to the Adductor magnus, the medial to the sacrotuberous ligament. The upper portion is subdivided into two areas by an oblique ridge which runs downwards and lateralwards; from the upper and lateral area the Semimembranosus arises; from the lower and medial, the long head of the Biceps femoris and the Semitendinosus.

The *inferior ramus* is the thin, flattened part of the ischium, which passes forwards from the superior ramus, and joins the inferior ramus of the os pubis, the junction being indicated by a raised line. Its *outer surface* is uneven for the origin of the Obturator externus and some of the fibres of the Adductor magnus; its *inner surface* forms part of the anterior wall of the pelvis, and gives attachment to the Sphincter urethræ membranaceæ. Its *lower border* is thick, rough, slightly everted, forms part of the outlet of the pelvis, and presents two slight ridges and an intervening space. The ridges are continuous with similar ones on the inferior ramus of the os pubis; to the outer is attached the deep layer of the superficial perinæal fascia (fascia of Colles), and to the inner the inferior fascia of the urogenital diaphragm. When traced backwards these two ridges join just behind the point of origin of the Transversus perinæi superficialis: to the intervening space, just in front of the point of junction of the ridges, the Transversus perinæi superficialis is attached, and in front of this the Ischiocavernosus and the crus penis vel clitoridis. Its *upper border* is thin and sharp, and forms part of the medial margin of the obturator foramen.

The *os pubis*, the anterior part of the hip-bone, is divisible into a body, and a superior and an inferior ramus.

The *body* forms one-half of the acetabulum, contributing by its *external surface* both to the *lunate surface* and to the acetabular fossa. Its *internal surface* enters into the formation of the wall of the lesser pelvis.

The *superior ramus* extends on the body to the median plane, where it articulates with its fellow of the opposite side. It is conveniently described in two portions, viz. a medial flattened part and a narrow lateral prismoid portion.

The *medial portion* of the superior ramus, formerly described as the body of the os pubis, is somewhat quadrilateral in shape, and presents for examination two surfaces and three borders. The *anterior surface* is rough, directed downwards and lateralwards, and serves for the origin of various muscles. The Adductor longus arises from the upper and medial angle, immediately below the crest; lower down, the Obturator externus, the Adductor brevis, and the upper part of the Gracilis take origin. The *posterior surface*, convex from above downwards, concave from side to side, is smooth, and forms part of the anterior wall of the pelvis. It gives origin to parts of the Levator ani and Obturator internus, and attachment to the puboprostatic ligaments and to a few muscular fibres prolonged from the bladder. The *upper border* presents a prominent tubercle, the *pubic tubercle* (pubic spine), which projects forwards; the inferior crus of the subcutaneous inguinal ring (external abdominal ring), and the inguinal ligament (Poupart's ligament) are attached to it. Passing upwards and lateralwards from the pubic tubercle is a well-defined ridge, the *pecten pubis*, which forms a part of the brim of the lesser pelvis; to it are attached a portion of the inguinal falx (conjoined tendon of Obliquus internus and Transversus), the lacunar ligament (Gimbernat's ligament), and the reflected inguinal ligament (triangular fascia). Medial to the pubic tubercle is the *crest*, which extends from the tubercle to the medial border of the bone; it affords attachment to the inguinal falx, and to the Rectus abdominis and Pyramidalis. The point of junction of the crest with the medial border of the bone is called the *angle*; to it, as well as to the symphysis, the superior crus of the subcutaneous inguinal ring is attached. The *medial border* is articular; it is oval, and is

marked by eight or nine transverse ridges, or a series of nipple-like processes arranged in rows; they serve for the attachment of a thin layer of cartilage, which is fixed to that of the opposite pubic bone by the *interpubic fibrocartilaginous lamina*. The *lateral border* presents a sharp margin, the *obturator crest*, which forms part of the circumference of the obturator foramen and affords attachment to the *obturator membrane*.

The *lateral portion* of the superior ramus has three surfaces: superior, inferior, and posterior; between the superior and posterior surfaces is a continuation of the pecten pubis, already mentioned as commencing at the pubic tubercle. The *superior surface*, in front of this line, is triangular in form, wider laterally than medially, and covered by the Pectineus. It is bounded laterally by a rough eminence, the *iliopectineal eminence*, which indicates the junction of the ilium and os pubis, and below by a prominent ridge which extends from the anterior margin of the acetabular notch to the pubic tubercle. The *inferior surface* forms the upper boundary of the obturator foramen, and presents, laterally, a broad, deep, groove, the *obturator groove*, for the passage of the obturator vessels and nerve; and medially, a sharp margin which is continuous below with the obturator crest; it gives attachment to the obturator membrane. The *posterior surface* constitutes part of the anterior boundary of the lesser pelvis. It is smooth, convex from above downwards, and affords origin to some fibres of the Obturator internus.

The *inferior ramus* is thin and flattened. It passes lateralwards and downwards from the medial part of the superior ramus, narrows as it descends and joins with the inferior ramus of the ischium below the obturator foramen. Its *anterior surface* is rough for the origin of muscles—the Gracilis along its medial border, a portion of the Obturator externus near the obturator foramen, and between these two muscles, the Adductores brevis and magnus, the former being the more medial. The *posterior surface* is smooth, and gives origin to the Obturator internus, and, close to the medial margin, to the Sphincter urethræ membranaceæ. The *medial border* is thick, rough, and everted, especially in females. It presents two ridges, separated by an intervening space. The ridges extend downwards, and are continuous with similar ridges on the inferior ramus of the ischium; to the medial is reached the superficial perineal fascia (fascia of Colles), and to the lateral the inferior fascia of the urogenital diaphragm. The *lateral border* is thin and sharp, forms part of the circumference of the obturator foramen, and gives attachment to the obturator membrane.

The *acetabulum* is a deep, cup-shaped, hemispherical depression, which looks downwards, lateralwards, and forwards. It is formed medially by the os pubis, above by the ilium, laterally, and below by the ischium; a little less than two-fifths is contributed by the ilium, a little more than two-fifths by the ischium, and one-fifth by the os pubis. It is surrounded by a prominent, uneven rim, which is thick and strong above and serves for the attachment of the glenoidal labrum (cylindroid growth), which contracts the orifice of the acetabulum, and deepens the surface for articulation. It presents below, a deep notch, the *acetabular notch*, which is continuous with a circular non-articular depression, the *acetabular fossa*, at the bottom of the cavity; this fossa is perforated by apertures for vessels, and lodges a mass of fat. The notch is converted into a foramen by the transverse acetabular ligament, and through the foramen nutrient vessels and nerves enter the joint; the margins of the notch serve for the attachment of the ligamentum teres. The rest of the acetabulum is formed by a curved articular surface, the *lunate surface*, for articulation with the head of the femur.

The *obturator foramen* is an aperture between the ischium and os pubis. In the male it is large and of an oval form, its longest diameter slanting obliquely from before backwards; in the female it is smaller, and more triangular. It is bounded by a thin, uneven margin, to which the obturator membrane is attached, and presents, superiorly, a deep groove, the *obturator groove*, which runs downwards and medialwards from the pelvis. This groove is converted into a canal by a ligamentous band, a specialised part of the obturator membrane, attached to two tubercles: one, the *posterior obturator tubercle* on the anteroinferior border of the ischium, just below the acetabular notch; the other, the *anterior obturator tubercle*, on the obturator crest of the superior

ramus of the os pubis. Through the canal the obturator vessels and nerve pass out of the pelvis.

Structure.—The thicker parts of the hip-bone consist of spongy substance, enclosed between two layers of compact bone; the thinner parts, as at the bottom of the acetabulum and centre of the iliac fossa, are usually semitransparent, and composed entirely of compact bone.

Ossification (fig. 400).—The hip-bone is ossified from eight centres: three primary, one each for the ilium, ischium, and os pubis; and five secondary, one each for the crest of the ilium, the anterior inferior iliac spine (said to occur more frequently in the male than in the female), the tuberosity of the ischium, the pubic symphysis (more frequent in the female than in the male), and one or more for the Y-shaped

FIG. 400.—Plan of ossification of the hip-bone.

By eight centres { Three primary (ilium, ischium, and os pubis)
Five secondary

The three primary centres unite through the Y-shaped piece about puberty.
Secondary centres appear about puberty, and unite about 25th year.

piece at the bottom of the acetabulum. The centres appear in the following order: in the ilium, immediately above the greater sciatic notch, about the eighth or ninth week of foetal life; in the superior ramus of the ischium, about the third month; in the superior ramus of the os pubis, between the fourth and fifth months. At birth, the iliac crest, the greater part of the acetabulum, the ischial tuberosity, and the inferior rami of the ischium and os pubis are cartilaginous. By the seventh or eighth year, the inferior rami of the os pubis and ischium are almost completely united by bone. By the twelfth year, the three primary centres have extended their growth into the bottom of the acetabulum, and are there separated from each other by a Y-shaped portion of cartilage, which now presents traces of ossification, often by two or more centres. One of these, the *os acetabuli*, forms the pubic part of the acetabulum and fuses with the main parts of the bone about puberty. The ilium and ischium then become joined, and lastly the os pubis and ischium, through the intervention of this Y-shaped portion. At about the age of puberty, ossification takes place in each of the remaining portions, and they join with the rest of the bone between the twentieth and twenty-fifth years. Separate centres are frequently found for the tubercle, crest and angle of the os pubis, and the spine of the ischium.

THE PELVIS

The **pelvis**, so called from its resemblance to a basin, is a massive bony ring, interposed between the movable segments of the vertebral column which it supports, and the lower limbs upon which it rests; it is composed of the two hip-bones laterally and in front, and the sacrum and coccyx behind. It is divided into the greater and the lesser pelvis by an oblique plane passing through the prominence of the sacrum behind, the arcuate line and pecten pubis laterally, and the upper margin of the symphysis pubis in front. The circumference of this plane is termed the *linea terminalis* or *pelvic brim*.

The **greater pelvis** (*pelvis major*), the expanded portion of the cavity above and in front of the pelvic brim, is formed on either side by the ilium and the ala of the sacrum.

The **lesser pelvis** (*pelvis minor*) is that part of the pelvic cavity which lies below and behind the pelvic brim. Its bony walls are more complete than

FIG. 401.—Diameters of superior aperture of lesser pelvis (female).

those of the greater pelvis. It possesses an inlet bounded by the superior circumference, an outlet bounded by the inferior circumference, and a cavity.

The *superior circumference* forms the brim of the pelvis, the included space being called the *superior aperture* or *inlet* (fig. 401). The superior aperture is somewhat heart-shaped, obtusely pointed in front, diverging on either side, and encroached upon behind by the forward projection of the promontory of the sacrum. It has three principal diameters: anteroposterior, transverse, and oblique. The *anteroposterior* or *conjugate diameter* extends from the sacrovertebral angle to the symphysis pubis: its average measurement is about 110 mm. in the female. The *transverse diameter* extends from the middle of the brim on one side to the same point on the opposite side; its average measurement is about 135 mm. in the female. The *oblique diameter* extends from the iliopectineal eminence to the opposite sacroiliac articulation; its average measurement is about 125 mm. in the female.

The *cavity* of the lesser pelvis is bounded in front and below by the pubic rami and symphysis; above and behind, by the pelvic surfaces of the sacrum and coccyx; laterally by a smooth, quadrangular area of bone, formed by the inner surfaces of the body and superior ramus of the ischium and of the body of the ilium. From this description, it will be seen that the cavity of the lesser pelvis is a short, curved canal, considerably deeper behind than in front. It contains, in the recent subject, the sigmoid (pelvic) colon, rectum, bladder, and some of the organs of generation. The rectum is placed at the

back of the pelvis, in the curve of the sacrum and coccyx ; the urinary bladder is in front, behind the pubic symphysis. In the female, the uterus and vagina are placed between the rectum and the urinary bladder.

The *lower circumference* of the pelvis is very irregular ; the space enclosed by it is named the *inferior aperture* or *outlet* (fig. 402), and is bounded behind by the apex of the coccyx, and laterally by the ischial tuberosities. These eminences are separated by three notches : one in front, the *pubic arch*, formed by the convergence of the inferior rami of the ischium and os pubis on either side. The other notches, one on either side, are formed by the sacrum and coccyx behind, the ischium in front, and the ilium above : they are called the *sciatic notches* ; in the natural state they are converted into foramina by the sacrotuberous and sacrospinous ligaments. When the ligaments are present, the inferior aperture of the pelvis is lozenge-shaped, and is bounded, in front, by the arcuate pubic ligament and the inferior rami of the ossa pubis and ischia ; laterally, by the ischial tuberosities ; behind, by the sacrotuberous ligaments and the tip of the coccyx.

FIG. 402.—Diameters of inferior aperture of lesser pelvis (female).

The *anteroposterior diameter* of the inferior aperture of the pelvis extends from the apex of the coccyx to the lower part of the pubic symphysis ; its measurement is from 90 to 115 mm. in the female. It varies with the length of the coccyx, and is capable of increase or diminution, on account of the mobility of that bone. The *transverse diameter*, measured between the posterior parts of the ischial tuberosities, is about 115 mm. in the female.*

Axes (fig. 403).—A line at right angles to the plane of the superior aperture at its centre would, if prolonged, pass through the umbilicus above and the middle of the coccyx below : the axis of the superior aperture is therefore directed downwards and backwards. The axis of the inferior aperture, produced upwards, would touch the base of the sacrum, and is directed downwards and slightly backwards. The axis of the cavity—i.e. an axis at right angles to a series of planes between those of the superior and inferior apertures—is curved like the cavity itself : this curve is parallel to that of the sacrum and coccyx, and its extremities are indicated by the central points of the superior and inferior apertures.

Position of the pelvis (fig. 403).—In the erect posture, the pelvis is placed obliquely with regard to the trunk : the plane of the superior aperture forms with the horizontal an angle of from 50° to 60°, and that of the inferior

* The measurements of the pelvis given above are fairly accurate, but different figures are given by various authors, no doubt due mainly to differences in the physique and stature of the population from whom the measurements have been taken.

aperture one of about 15° . The pelvic surface of the symphysis pubis looks upwards and backwards, the concavity of the sacrum and coccyx downwards and forwards. The position of the pelvis in the erect posture may be indicated by holding it so that the anterior superior iliac spines and the front of the top of the symphysis pubis are in the same vertical plane.

Differences between the male and female pelvises.—The female pelvis (fig. 405) is distinguished from that of the male (fig. 404) by its bones being more delicate and its depth less. The whole pelvis is less massive, and its muscular impressions are not so marked. The ilia are larger, their posterior borders are more rounded and less vertical, and the anterior iliac spines more widely separated; hence the greater lateral prominence of the hips. The superior aperture of the lesser pelvis is larger in the female than in the male; it is more nearly circular, and its obliquity is greater. The cavity is shallower and wider; the sacrum is shorter, wider, and its upper part is less curved; the obturator foramina are triangular in shape and are smaller in size than in the male. The inferior aperture is larger and the coccyx more movable. The pre-auricular sulci are more commonly present and better marked. The sciatic notches are wider and shallower, and the spines of the ischia project less inwards. The acetabula are wider apart, smaller and look

FIG. 403.—Median sagittal section of pelvis.

FIG. 404.—Male pelvis.

more distinctly forwards (Derry *). The ischial tuberosities are also wider apart, and are more everted. The depth of the pubic symphysis is less, and the pubic arch is wider and more rounded than in the male, where it is an

* *Journal of Anatomy and Physiology*, vol. xliii.

angle rather than an arch. The auricular surfaces for articulation with the sacrum usually involve only two vertebræ, whereas in the male they extend over two and a half or three vertebræ.

The size of the pelvis varies not only in the two sexes, but also in different members of the same sex, and does not appear to be influenced in any way by the height of the individual. Women of short stature, as a rule, have broad pelves. Occasionally the pelvis is contracted in all its dimensions, and its diameters may be as much as 12·5 mm. less than the average, and this even in well-formed women of average height. The principal divergences, however, are found at the superior aperture, and affect the relation of the anteroposterior to the transverse diameter. Thus the superior aperture may be elliptical either in a transverse or an anteroposterior direction, the transverse diameter in the former, and the anteroposterior in the latter, greatly exceeding the other diameters; in other instances it is almost circular.

FIG. 405.—Female pelvis.

In the *fœtus*, and for several years after birth, the pelvis is small in proportion to that of the adult, and the projection of the sacrovertebral angle less marked. The characteristic differences between the male and female pelves are distinctly indicated as early as the fourth month of foetal life

Applied Anatomy.—There is arrest of development in the bones of the pelvis in cases of extroversion of the bladder; the anterior part of the pelvic girdle is deficient, the superior rami of the pubic bones are imperfectly developed, and the symphysis is absent. The pubic bones are separated to the extent of from two to four inches, the superior rami shortened and directed forwards, and the obturator foramina diminished in size, narrowed, and turned outwards. The iliac bones are straightened out more than normal. The sacrum is very peculiar. The lateral curve, instead of being concave, is flattened out or even convex, with the iliosacral facets turned more outward than normal, while the vertical curve is straightened.*

Fractures of the pelvis are divided into those of the greater and those of the lesser pelvis. Fractures of the greater pelvis vary in extent; a small portion of the crest may be broken, or one of the spinous processes may be torn off, or the bone may be extensively comminuted. This latter accident is the result of some crushing violence, and may be complicated with fracture of the lesser pelvis. These cases may be accompanied by injury to the intestine as it lies in the hollow of the bone, or to the iliac vessels as they course along the margin of the lesser pelvis. A fracture of the lesser pelvis generally occurs through the superior ramus of the os pubis and the inferior ramus of the ischium, as these are the weakest parts of the bony ring, and may be caused either by crushing violence applied in an anteroposterior direction, when the fracture occurs from direct

* Wood. *Heath's Dictionary of Practical Surgery*, i. 426.

force, or by compression laterally, when the acetabula are pressed together and the bone gives way in the same place from indirect violence. Sometimes both sides of the pelvis are fractured, and it is in these cases that the contained viscera are likely to be injured: the urethra, the bladder, the rectum, the small intestines, the vagina, and even the uterus, have all been lacerated by displaced fragments. Fractures of the acetabulum are occasionally met with: either a portion of the rim may be broken off, or a fracture may take place through the bottom of the cavity, and the head of the femur be driven into the pelvic cavity. Separation of the Y-shaped cartilage at the bottom of the acetabulum may also occur in the young subject, splitting the bone into its three portions.

The coccyx is not infrequently displaced forwards to nearly a right angle with the sacrum by a kick or by a fall backwards. The condition is attended with great pain in walking and on making any expiratory effort, such as coughing, defæcation, etc., because the Coccygei and Levatores ani which form the pelvic diaphragm are attached to this bone. Such injuries often give rise to severe persistent pain, which is exceedingly intractable and difficult of cure. The condition is known as *coccygodynia*, and for its relief removal of the coccyx has been practised.

The pelvic bones often undergo important deformity in *rickets*, the effects of which in the adult woman may seriously interfere with child-bearing, demanding the premature induction of labour at a time when the fœtus will not yet be too large for delivery through the contracted or deformed pelvis. The deformity is due mainly to the weight of the trunk, which presses on the sacrovertebral angle and greatly increases it, so that the anteroposterior diameter of the pelvis is diminished, and may measure as little as 40 mm., the entrance into the pelvis becoming reniform. In other cases all the pelvic bones give way, so that a general diminution in all the diameters of the pelvis results, the pelvic entrance becoming triangular or asymmetrical. If the pubic symphysis be forced forwards, the rickety pelvis may even come to resemble closely the deformed pelvis of *osteomalacia*; in this disease the weight of the trunk causes an increase in the sacrovertebral angle, and a lessening of the anteroposterior diameter of the superior aperture, and at the same time the pressure of the heads of the femora on the acetabula causes these cavities, with the adjacent bone, to be pushed upwards and backwards, so that the oblique diameters of the pelvis are also diminished, and the cavity of the pelvis assumes a triradiate shape, with the symphysis pubis pushed forwards.

THE FEMUR

The femur (figs. 407 and 408), the longest and strongest bone in the skeleton, is cylindrical in the greater part of its extent. In the erect posture it is placed

FIG. 406.—Upper extremity of right femur, viewed from behind and above.

obliquely, being separated above from its fellow by an interval which corresponds to the breadth of the pelvis, but inclining gradually downwards and medialwards, so as to approach its fellow below, for the purpose of bringing the knee-joint near the line of gravity of the body. The degree of this inclination varies in different persons, and is greater in the female than in

FIG. 407.—Right femur. Anterior surface.

the male, on account of the greater breadth of the pelvis. The femur has a body and two extremities.

The upper extremity (fig. 406) comprises a head, a neck, and a greater and lesser trochanter.

The head is globular and forms rather more than a hemisphere; it articulates with the acetabulum of the hip-bone, and is directed upwards, medialwards, and a little forwards. Its surface is smooth, except at an ovoid depression, the *fovea capitis femoris*, which is situated a little below and behind the centre of the head, and gives attachment to the ligamentum teres of the hip-joint.

The neck is flattened anteroposteriorly; it connects the head with the body, and forms with the latter an angle of about 125° . The angle decreases during the period of growth, but after full growth has been attained it does not usually undergo any change; in the female, in consequence of the increased width of the pelvis, it is less than in the male. In addition to projecting upwards and medialwards from the body of the femur, the neck projects somewhat forwards; the amount of this forward projection is extremely variable, but on an average is from 12° to 14° .

The neck is contracted in the middle, and broader laterally than medially. The vertical diameter of the lateral half is increased by the obliquity of the lower edge, which slopes downwards to join the body at the level of the lesser trochanter; the medial half is smaller, and of a more circular shape. The anterior surface of the neck is perforated by numerous vascular foramina. Along the upper part, and encroaching on the line of junction of this surface with the head is a shallow, rough groove, best marked in elderly subjects; this groove lodges the orbicular fibres of the capsule of the hip-joint.

The *posterior surface* is more concave than the anterior, and usually exhibits a shallow, oblique groove for the tendon of the *Obturator externus*; the posterior part of the capsule of the hip-joint is attached to the neck about 1 cm. above the intertrochanteric crest. The *superior border*, short and thick, ends laterally at the greater trochanter, and is perforated by large foramina. The *inferior border*, long and narrow, curves a little backwards, and ends at the lesser trochanter.

The *greater trochanter* is a large, irregular, quadrilateral eminence, at the junction of the neck and the upper part of the body. It is directed upwards, lateralwards, and a little backwards, and, in the adult, its superior border is on a level with the centre of the head. It has two surfaces and four borders. The *lateral surface*, quadrilateral in form, is broad, rough, convex, and marked by a diagonal impression, which extends from the posterosuperior to the anteroinferior angle, and serves for the insertion of the tendon of the *Glutæus medius*. Above the impression is a triangular surface, sometimes rough for part of the tendon of the same muscle, sometimes smooth for the interposition of a bursa between the tendon and the bone. Below and behind the diagonal impression is a smooth, triangular surface, over which the tendon of the *Glutæus maximus* plays, a bursa being interposed. The *medial surface* is of much less extent than the lateral; at its base is a deep depression, the *trochanteric fossa*, for the insertion of the tendon of the *Obturator externus*, and above and slightly in front of this an impression for the insertion of the *Obturator internus* and *Gemelli*. The *superior border* is free; it is thick and irregular, and near its centre is an impression for the insertion of the *Piriformis*. The *inferior border* corresponds to the line of junction of the base

FIG. 408.—Right femur. Posterior surface.

of the trochanter with the lateral surface of the body; it is marked by a rough, prominent, slightly curved ridge, which gives origin to the upper part of the *Vastus lateralis*. The *anterior border* is prominent and somewhat irregular; it affords insertion at its lateral part to the *Glutæus minimus*. The *posterior border* is a prominent rounded edge, which bounds the back of the trochanteric fossa, and forms the upper part of the intertrochanteric crest.

The *lesser trochanter* is a conical eminence which projects from the lower and posterior part of the base of the neck. From it three borders extend; two of these are directed upwards—a *medial* continuous with the lower border of the neck; a *lateral* with the intertrochanteric crest; the third or *inferior* is continuous with the middle division of the *linea aspera*. The *summit* of the trochanter is rough, and gives insertion to the tendon of the *Psoas major*.

A prominence, of variable size, occurs at the junction of the upper part of the front of the neck with the greater trochanter, and is called the *tubercle* of the femur. Running downwards and medialwards from it is the *intertrochanteric line*; it winds round the medial side of the body of the bone, in front of and below the lesser trochanter, and ends about 5 cm. below this eminence in the *linea aspera*. Its upper half is rough, and affords attachment to the iliofemoral ligament of the hip-joint; its lower half is less prominent, and gives origin to the upper part of the *Vastus medialis*. On the posterior surface a prominent ridge, the *intertrochanteric crest*, runs obliquely downwards and medialwards from the summit of the greater trochanter to the lesser trochanter; its upper half forms the posterior border of the greater trochanter. A slight ridge, the *linea quadrata*, is sometimes seen commencing about the middle of this crest, and reaching vertically downwards for about 5 cm. along the back part of the body; it gives attachment to the *Quadratus femoris* and a few fibres of the *Adductor magnus*; as a rule, there is merely a slight thickening about the middle of the intertrochanteric crest, marking the attachment of the upper part of the *Quadratus femoris*.

The *body* or *shaft*, almost cylindrical in form, is a little broader above than in the centre, broadest and somewhat flattened from before backwards below. It is slightly arched, so as to be concave behind, where it is strengthened by a prominent longitudinal crest, the *linea aspera*. It has three borders and three surfaces. Of the borders, one, the *linea aspera*, is posterior, one is medial, and the other, lateral.

The *linea aspera* (fig. 408) is a longitudinal crest, on the middle third of the bone; it has a medial and a lateral lip, and a narrow, rough, intermediate line. Three ridges, lateral, intermediate and medial, run upwards from the *linea aspera*. The lateral ridge is very rough, and ascends to the base of the greater trochanter; it is termed the *gluteal tuberosity*, and gives insertion to part of the *Glutæus maximus*; its upper part is often elongated into a roughened crest, on which a rounded tubercle, the *third trochanter*, is occasionally developed. The intermediate ridge or *pectineal line* is continued to the base of the lesser trochanter and gives insertion to the *Pectineus*. The medial ridge is lost in the intertrochanteric line. The lips of the *linea aspera* diverge below and are prolonged as two epicondylar ridges, enclosing between them a triangular area, the *popliteal surface*, which forms the upper part of the floor of the popliteal fossa. The lateral epicondylar ridge is the more prominent, and descends to the summit of the lateral condyle. The medial ridge is less marked, especially at its upper part, where it is crossed by the femoral artery; it ends below, at the summit of the medial condyle, in the *adductor tubercle*, which affords insertion to the tendon of the *Adductor magnus*. In about 80 per cent. of specimens a rounded tubercle is present on the lower part of the popliteal surface, just above the medial condyle; to it the upper part of the medial head of the *Gastrocnemius* is attached.*

From the medial lip of the *linea aspera* and its prolongations above and below, the *Vastus medialis* arises; and from the lateral lip and its upward prolongation, the *Vastus lateralis* takes origin. The *Adductor magnus* is inserted into the *linea aspera*, and to its lateral prolongation above, and its medial prolongation below. Between the *Vastus lateralis* and the *Adductor magnus* the *Glutæus maximus* is attached above, and the short head of the

* F. G. Parsons, *Journal of Anatomy and Physiology*, vol. xlviii. p. 267, and J. S. B. Stopford, *Journal of Anatomy and Physiology*, vol. xlix. p. 80.

Biceps femoris below. Between the Adductor magnus and the Vastus medialis four muscles are inserted: the Iliacus and Pectineus above; the Adductor brevis and Adductor longus below. A little below the middle of the linea aspera is the orifice of the nutrient canal, which is directed obliquely upwards.

FIG. 409.—Lower extremity of right femur, viewed from below.

The *lateral* and *medial borders* of the femur are only slightly marked: the lateral extends from the anteroinferior angle of the greater trochanter to the front of the lateral condyle: the medial from the intertrochanteric line, at the level of the lesser trochanter, to the front of the medial condyle.

The *anterior surface* of the body is between the lateral and medial borders: it is smooth, convex, broader above and below than in the centre. The Vastus intermedius arises from its upper three-fourths, and from the upper part of its lower fourth the Articularis genus takes origin. The *lateral surface* is between the lateral border and the linea aspera: it is continuous above with the lateral surface of the greater trochanter, below with that of the lateral condyle: the

FIG. 410.—Lateral surface of lower end of right femur.

Vastus intermedius arises from its upper three-fourths. The *medial surface* is between the medial border and the linea aspera: it is continuous above with the lower border of the neck, below with the medial side of the medial condyle: it is covered by the Vastus medialis.

The **lower extremity** (fig. 409), larger than the upper, consists of two oblong eminences known as the *condyles*; in front, these are but slightly prominent, and are separated by a smooth shallow articular depression called

the *patellar surface*; behind, they project considerably, and are separated by a deep notch, the *intercondyloid fossa*. The *lateral condyle* is the more prominent anteriorly, and is the broader both in its anteroposterior and transverse diameters. The *medial condyle* projects to a lower level than the lateral, when the femur is held with its body perpendicular; when, however, the bone is in its natural oblique position the lower surfaces of the two condyles lie in the same horizontal plane. The condyles are not quite parallel with one another; the long axis of the lateral is almost directly anteroposterior, but that of the medial runs backwards and medialwards. Their opposed surfaces are small, rough, and concave, and form the walls of the intercondyloid fossa; this fossa is limited above by a ridge, the *intercondyloid line*, and below by the central

FIG. 411.—Longitudinal section of head and neck of femur.

part of the posterior margin of the patellar surface. The *posterior cruciate ligament* of the knee-joint is attached to the lower and front part of the medial wall of the fossa, and the *anterior cruciate ligament* to the upper and posterior part of its lateral wall. Each condyle is surmounted by an elevation, the *epicondyle*. The *medial epicondyle* is a large convex eminence to which the *tibial collateral ligament* of the knee-joint is attached. At its upper part is the *adductor tubercle*, already referred to, and behind it is a rough impression which gives origin to the medial head of the *Gastrocnemius*. The *lateral epicondyle* (fig. 410), smaller and less prominent than the medial, gives attachment to the *fibular collateral ligament* of the knee-joint. Directly below it is a small depression from which a deep, oblique groove curves upwards and backwards to the posterior extremity of the condyle. This groove is separated from the articular surface of the condyle by a rounded lip, across the anterior part of which a vertical shallow groove descends from the depression. In the recent state these grooves are covered with cartilage. The *Popliteus* arises from the depression below the epicondyle; its tendon lies in the oblique groove when the knee is flexed and in the vertical groove when the knee is extended.

Above and behind the lateral epicondyle is an area for the origin of the lateral head of the *Gastrocnemius*, above and medial to which the *Plantaris* arises.

The *articular surface* of the lower end of the femur occupies the anterior, inferior, and posterior surfaces of the condyles. Its front part is named the *patellar surface* and articulates with the patella; it presents a median groove between two convexities, the lateral of which is broader, more prominent, and ascends farther than the medial. The lower and posterior parts of the articular surface constitute the *tibial surfaces* for articulation with the corresponding condyles of the tibia and the menisci of the knee-joint. These surfaces are separated from one another by the intercondyloid fossa and from the patellar surface by faint grooves which extend obliquely across the condyles. The lateral groove is the better marked; it runs lateralwards and slightly forwards from the front part of the intercondyloid fossa, and expands to form a triangular depression which rests upon the anterior portion of the lateral meniscus when the knee-joint is fully extended. The medial groove is less distinct than the lateral, and exists only on the medial part of the condyle; it receives the anterior edge of the medial meniscus when the knee-joint is extended. Where the groove ceases laterally the patellar surface is seen to be continued backwards as a semilunar area close to the anterior part of the intercondyloid fossa; this semilunar area articulates with the medial vertical facet of the patella in forced flexion of the knee-joint. The tibial surfaces of the condyles are convex from side to side and from before backwards. Each presents a double curve, its posterior segment being an arc of a circle, its anterior part of a cycloid.*

Structure.—The body of the femur is a cylinder of compact bone, hollowed by a large medullary canal. The wall of the cylinder is thick and dense in the middle third of the body, where the bone is narrowest and the medullary canal best formed; but above and below this the wall becomes thinner, while the medullary canal is gradually filled up by spongy substance, so that the upper (fig. 411) and lower ends of the body, and the articular extremities more especially, consist of spongy substance, invested by a thin compact layer.

The cancelli in the ends of the femur are disposed along the lines of greatest pressure and tension. In the upper end (fig. 412) the chief lamellæ are arranged in the following manner. A series of bony planes at right angles to the articular surface of the head converge to a central dense wedge; this wedge is supported by strong lamellæ which extend to the sides of the neck and are specially marked along its upper and lower borders. Any force therefore applied to the head of the femur is transmitted directly to the central wedge and thence to the junction of the neck with the body. This junction is specially strengthened by a series of dense lamellæ which extend from the lesser trochanter to the lateral end of the superior border of the neck; this arrangement will obviously oppose considerable resistance to either tensile or shearing force. A smaller bar stretching across the junction of the greater trochanter with the neck and body resists the shearing force of the muscles attached to this prominence. These two bars, one at the junction of body and neck, the other at the junction of body and greater trochanter, form the upper layers of a series of arches which extend across between the sides of the body and transmit to the body forces applied to the upper end of the bone. In the spongy substance of the neck is a thin vertical plate of bone, the *calcar femorale*, which springs from the compact wall of the body in the region of the *linea aspera*. Medially it is attached to the inner surface of the posterior wall of the neck of the bone; laterally it continues the plane of the posterior wall of the neck into the greater trochanter, where it shades off into the general spongy

FIG. 412.—Scheme showing disposition of principal cancellous lamellæ in upper extremity of femur.

* A *cycloid* is a curve traced by a point in the circumference of a wheel when the wheel is rolled along in a straight line.

substance. It is thus situated in a plane anterior to the intertrochanteric crest and to the base of the lesser trochanter (fig. 413).

In the lower end, the cancelli spring on all sides from the inner surface of the cylinder, and descend in a perpendicular direction to the articular surface, the cancelli being strongest and having a more accurately perpendicular course above the condyles. In addition to this, there are horizontal planes of cancellous tissue, so that the spongy substance in this situation presents an appearance of being mapped out into a series of cubical spaces.

Ossification (figs. 414, 415, 416).—The femur is ossified from five centres: one each for the body, head, greater trochanter, lesser trochanter, and lower extremity.

FIG. 413.—Oblique section of upper extremity of femur showing calcar femorale.

FIG. 414.—Plan of ossification of the femur. From five centres.

Except the clavicle, it is the first of the long bones to show traces of ossification; the latter begins in the middle of the body in the seventh week of foetal life, and extends upwards and downwards. The secondary centres appear as follows: in the lower extremity, during the ninth month of foetal life (from this centre the condyles and epicondyles are formed); in the head at the end of the first year after birth; in the greater trochanter during the fourth year; and in the lesser trochanter between the thirteenth and fourteenth years. The epiphyses, derived from the secondary centres, fuse independently with the body after puberty; the lesser trochanter joins first, then the greater, then the head, and, lastly, the inferior extremity which is not united until the twentieth year.

Applied Anatomy.—The lower end of the femur is the only epiphysis in which ossification has commenced at the time of birth. The presence of this ossific centre is, therefore,

a proof, in a newly-born child found dead, that the child has arrived at the full period of uterogestation, and is always relied upon in medico-legal investigations. The position of the epiphysial plate should be carefully noted. It is on a level with the adductor tubercle, and the epiphysis does not, therefore, form the whole of the synovial covered portion of the lower end of the bone. It is essential to bear this point in mind in performing excision of the knee, since growth in length of the femur takes place chiefly from the lower epiphysis, and any interference with the epiphysial cartilage in a young child would involve such ultimate shortening of the limb, from want of growth, as to render the limb almost useless. Separation of the lower epiphysis may take place up to the age of twenty, at which time it becomes completely joined to the body of the bone; but, as a matter of fact, few cases occur after the age of sixteen or seventeen. The epiphysis of the head of the femur is the seat of origin, in a large number of cases, of tuberculous disease of the hip-joint. In the majority of cases the disease begins in the highly vascular and growing

FIG. 415.—Epiphysial lines of femur in a young adult. Anterior aspect.

The lines of attachment of the articular capsules are in blue.

FIG. 416.—Epiphysial lines of femur in a young adult. Posterior aspect.

The lines of attachment of the articular capsules are in blue.

tissue at the end of the body in the neighbourhood of the epiphysial cartilage, and extends into the joint. The epiphysis for the head is entirely intracapsular.

Fractures of the femur are divided, like those of the other long bones, into fractures of the upper end; of the body; and of the lower end. The fractures of the upper end may be classified into (1) fracture of the neck; (2) fracture at the junction of the neck with the greater trochanter; (3) fracture of the greater trochanter; and (4) separation of the epiphysis, either of the head or of the greater trochanter. The first of these, fracture of the neck, is usually termed *intracapsular* fracture, but this is scarcely a correct designation, as, owing to the attachment of the articular capsule, the fracture is partly within and partly without the capsule when the fracture occurs at the lower part of the neck. It generally takes place in old people, principally women, and usually from a very slight degree of indirect violence. Probably the main cause of its occurrence in old people is the senile degenerative change which takes place in the bone. Merkel believes that it is mainly due to the absorption of the *calcar femorale*. As a rule the fragments become united by fibrous tissue, but frequently no union takes place, and the opposed surfaces become smooth and eburnated.

Fractures at the junction of the neck with the greater trochanter are usually termed *extracapsular*, but this designation is also incorrect, as the fracture is partly within the capsule, which is attached in front to the intertrochanteric line below the line of fracture. These fractures are produced by direct violence to the greater trochanter, as from a fall laterally on the hip. From the manner in which the accident is caused the neck of the bone is driven into the trochanter, where it may remain impacted or the trochanter may be split into two or more fragments, disimpaction resulting.

Fractures of the body may occur at any part, but the most usual situation is at or near the centre of the bone. They may be caused by direct or indirect violence. Fractures of the upper third of the body are almost always the result of indirect violence, while those of the lower third are the result, for the most part, of direct violence. Fractures of the body are generally oblique, but they may be transverse, longitudinal, or spiral. The transverse fracture occurs most frequently in children. The fractures of the lower end of the femur include transverse fracture above the condyles, the most common; and this may be complicated by a vertical fracture between the condyles, constituting the T-shaped fracture. In these cases the popliteal artery is in danger of being wounded. Oblique fracture separating either the medial or lateral condyle, and a longitudinal incomplete fracture between the condyles, may also take place.

The femur and the bones of the leg are frequently the seat of acute osteomyelitis in children. This is no doubt due to their greater exposure to injury, which is often the exciting cause of this disease. Necrosis of portions of the diaphysis frequently ensue, especially in the region of the popliteal surface of the femur, and the disease may continue for years, great trouble being experienced with discharging sinuses which periodically close and reopen to allow of the exit of pieces of dead bone.

Tumours are not infrequently found growing from the femur: the most common forms being sarcoma, which may grow either from the periosteum or from the medullary tissue within the interior of the bone, and exostosis, which commonly originates in the neighbourhood of the epiphysal cartilage of the lower end. The periosteal sarcomata of the femur and most of the central growths are usually of a very high degree of malignancy, although the 'myeloid' growth, which is of but low malignancy, may also be found. The region of the lower epiphysal line is by far the commonest seat for all these tumours, and it should be noted that the lower epiphysis has the longest period of active growth, and that these tumours usually appear towards the end of the period of active growth of the bone.

Sarcomata about the upper end of the femur are seen occasionally, but very rarely in comparison with those at the lower end. Secondary carcinoma also occurs in this bone, most commonly due to a primary focus in the mamma, and spontaneous fracture of the bone may take place in these cases.

THE TIBIA

The tibia (figs. 418 and 419) is situated at the medial side of the leg, and, excepting the femur, is the longest bone of the skeleton. It is prismoid in form, expanded above, where it enters into the formation of the knee-joint, contracted in the lower third, and again enlarged, but to a lesser extent, below. It has a body and two extremities.

FIG. 417.—Upper surface of right tibia.

It enters into the formation of the knee-joint, contracted in the lower third, and again enlarged, but to a lesser extent, below. It has a body and two extremities.

The upper extremity (fig. 417) is expanded into two eminences, the *medial* and *lateral condyles*, the superior surfaces of which are smooth and articular. The medial articular surface, oval in shape, is slightly concave from side to side, and from before backwards; the lateral, nearly circular, is concave from side to side, but slightly convex from before backwards, especially at its posterior part, where it is prolonged on to

the posterior surface for a short distance. The central portions of these surfaces articulate with the condyles of the femur, while their peripheral portions support the menisci of the knee-joint, which here intervene between the two bones. Between the articular surfaces, nearer the posterior than the anterior part of the bone, is the *intercondyloid eminence* (tibial spine), surmounted on either side by a prominent tubercle, on the sides of which the

FIG. 418.—Bones of the right leg.
Anterior surface.

FIG. 419.—Bones of the right leg
Posterior surface.

articular surfaces are prolonged; in front of and behind the intercondyloid eminence are rough depressions, the *anterior* and *posterior intercondyloid fossæ*, for the attachment of the cruciate ligaments and the menisci of the knee-joint. The anterior surfaces of the condyles are continuous with one another, forming a large, triangular, somewhat flattened area; this area is perforated by vascular foramina, and ends below in an oblong elevation, the *tuberosity* of the tibia, which gives attachment to the *ligamentum patellæ*; a *bursa* intervenes between the deep surface of the ligament and the part of the bone immediately above the tuberosity. The *medial condyle* is grooved posteriorly, for the insertion of the tendon of the *Semimembranosus*; its medial surface, convex, rough and prominent, gives attachment to the posterior part of the *tibial collateral ligament*. The *lateral condyle* presents posteriorly a flat, nearly circular, articular facet, directed downwards, backwards, and lateralwards, for articulation with the head of the fibula. Its lateral surface is convex, rough and prominent in front: on it is an eminence, situated on a level with the upper border of the tuberosity and at the junction of its anterior and lateral surfaces, for the attachment of the *iliotibial tract* or *band of the fascia lata*. Just below this a slip from the tendon of the *Biceps femoris* is inserted, and a small part of the *Extensor digitorum longus* takes origin.

The *body or shaft* has three crests or margins and three surfaces.

The *anterior crest* or *shin*, the most prominent, begins above at the tuberosity, and ends below at the anterior margin of the medial malleolus. It is sinuous and prominent in its upper two-thirds, but smooth and rounded below; it gives attachment to the deep fascia of the leg.

The *medial margin* is smooth and rounded above and below, but more prominent in the centre; it begins at the posterior part of the medial condyle, and ends at the posterior border of the medial malleolus; its upper part gives attachment to the *tibial collateral ligament* of the knee-joint to the extent of about 5 cm., and insertion to some fibres of the *Popliteus*; from its middle third some fibres of the *Soleus* and *Flexor digitorum longus* take origin.

The *interosseous crest* gives attachment to the *crural interosseous membrane* (fig. 422) and is most distinct in the middle third of the bone; it begins above in front of the fibular articular facet, and bifurcates below to form the boundaries of a triangular rough surface, the *fibular notch*, for the attachment of the *interosseous ligament* connecting the tibia and fibula.

The *medial surface* is smooth, convex, and broader above than below; its upper third is covered by the aponeurosis derived from the tendon of the *Sartorius*, and by the tendons of the *Gracilis* and *Semitendinosus* which are inserted into this part of the bone; the rest of the surface is subcutaneous.

The *lateral surface* is narrower than the medial; on its upper two-thirds is a shallow groove for the origin of the *Tibialis anterior*; its lower third is smooth, convex, curves gradually forwards to the anterior aspect of the bone, and is covered by the tendons of the *Tibialis anterior*, *Extensor hallucis longus*, and *Extensor digitorum longus*, arranged in this order from the medial side.

At the upper part of the *posterior surface* (fig. 419) is a prominent ridge, the *popliteal line*, which descends obliquely from the fibular articular facet to the medial border, near the junction of its upper and middle thirds; the fascia covering the *Popliteus* muscle is attached to it, and parts of the *Soleus*, *Flexor digitorum longus*, and *Tibialis posterior* take origin from it. Above the line is a triangular area, into the greater part of which the *Popliteus* is inserted; immediately below the line is the *nutrient foramen*, which is large and directed obliquely downwards. The middle third of the posterior surface is divided into two areas by a vertical ridge which begins at the popliteal line and is usually well marked above, but indistinct below; the medial and broader area gives origin to the *Flexor digitorum longus*, the lateral and narrower to part of the *Tibialis posterior*. The lower part of the posterior surface is smooth and covered by the *Tibialis posterior*, *Flexor digitorum longus*, and *Flexor hallucis longus*.

The *lower extremity* is prolonged downwards on its medial side as a strong process, the *medial malleolus*. The *inferior articular surface* is quadrilateral, and articulates with the talus. It is broader in front than behind, concave from before backwards, and near the middle is traversed in this direction by a slight elevation. It is continuous with the articular surface on the lateral

side of the medial malleolus. The *anterior surface* is smooth and rounded above, and covered by the tendons of the Extensor muscles; at its lower margin is a furrow for the attachment of the articular capsule of the ankle-joint. The lateral part of the *posterior surface* is traversed by a shallow groove, directed obliquely downwards and medialwards, in which the tendon of the Flexor hallucis longus lies. On the *lateral surface* is a triangular rough depression, the *fibular notch*, for the attachment of the interosseous ligament connecting the tibia with the fibula; in the recent state, the lower border of this notch is occasionally covered with cartilage, and articulates with the fibula. The notch is bounded by two prominent borders, continuous above with the interosseous crest; their lower parts afford attachment to the anterior and posterior ligaments of the lateral malleolus.

The *medial malleolus* is a strong pyramidal process, flattened from side to side. Its medial surface is convex and subcutaneous; its *lateral* or articular

FIG. 420.—Plan of ossification of the tibia.
From three centres.

FIG. 421.—Epiphysial lines of tibia and fibula in a young adult.
Anterior aspect.

The lines of attachment of the articular capsules are in blue.

surface, smooth and slightly concave, articulates with the talus; its anterior border is rough, for the attachment of the anterior fibres of the deltoid ligament of the ankle-joint; on its *posterior border* is a broad groove, the *malleolar sulcus*, directed obliquely downwards and medialwards, and occasionally double; it lodges the tendons of the Tibialis posterior and Flexor digitorum longus. The *summit* of the malleolus is marked behind by a depression, for the attachment of the deltoid ligament.

Structure. The structure of the tibia is like that of the other long bones. The compact wall of the body is thickest at the junction of the middle with the lower one-third of the bone.

Ossification.—The tibia is ossified from three centres (figs. 420, 421): one for the body and one for either end. Ossification begins in the centre of the body about the seventh week of foetal life. The centre for the upper end appears before or shortly after birth, and from it a thin tongue-shaped process extends downwards

in front, to form the tuberosity (fig. 421); the centre for the lower end appears in the second year. The lower end joins the body at about the eighteenth year; the upper about the twentieth year. Two additional centres occasionally exist, one for the tongue-shaped process of the upper end, which forms the tuberosity, and one for the medial malleolus.

THE FIBULA

The **fibula** (figs. 418 and 419) is placed on the lateral side of the tibia, with which it is connected above and below. In proportion to its length it is the most slender of all the long bones. Its upper extremity articulates with the back of the lateral condyle of the tibia, below the level of the knee-joint. The bone inclines a little forwards so that its lower extremity or lateral malleolus is on a plane anterior to that of the upper end; it projects below the tibia, and forms the lateral part of the ankle-joint.

The **upper extremity** or **head** is of an irregular quadrate form, and has a flattened articular surface, directed upwards, forwards, and medialwards, for articulation with the lateral condyle of the tibia. On its lateral side is a thick and rough prominence, continued behind into a pointed eminence, the *apex* or *styloid process*, which projects upwards from the posterior part of the head.

FIG. 422.—Transverse section of tibia and fibula, showing attachment of interosseous membrane.

The prominence, at its upper and lateral part, gives attachment to the tendon of the *Biceps femoris* and to the *fibular collateral ligament* of the knee-joint, the ligament dividing the tendon into two parts. The remaining part of the head is rough, for the attachment of muscles and ligaments; in front is a tubercle for the origin of the upper fibres of the *Peroneus longus*, and a surface for the attachment of the *anterior ligament* of the head of the bone; behind, another tubercle, for the attachment of the *posterior ligament* of the head and a few fibres of the *Soleus*.

The **body** or **shaft** has four borders—*anterolateral*, *anteromedial*, *posterolateral*, and *posteromedial*; and four surfaces—*anterior*, *posterior*, *medial*, and *lateral*.

The *anterolateral border* begins above in front of the head, runs vertically downwards to a little below the middle of the bone, and then curving lateralwards, bifurcates to embrace a triangular subcutaneous surface immediately above the lateral malleolus. This border gives attachment to the *anterior fibular intermuscular septum* which separates the *Extensor muscles* on the anterior surface of the leg from the *Peroneus longus* and *Peroneus brevis* on the lateral surface.

The *anteromedial border*, or *interosseous crest*, is close to the medial side of the *anterolateral border*, and runs nearly parallel with it in the upper third of its extent, but diverges from it in the lower two-thirds. It begins above just below the head of the bone, and is sometimes quite indistinct for about 2.5 cm.; it ends at the apex of a rough triangular surface which is situated

above the articular facet of the lateral malleolus. It serves for the attachment of the crural interosseous membrane (fig. 422) which separates the extensor muscles in front from the flexor muscles behind.

The posterolateral border is prominent; it begins above at the styloid process of the head and ends below in the posterior border of the lateral malleolus. It is directed lateralwards above, backwards in the middle of its course, backwards and a little medialwards below, and gives attachment to the posterior fibular intermuscular septum which separates the Peronæi on the lateral surface from the Flexor muscles on the posterior surface.

The posteromedial border, sometimes called the oblique line, begins above at the medial side of the head and ends by joining the interosseous crest at the lower fourth of the bone; it is well marked and prominent at the

FIG. 423.—Lower extremity of right fibula.
Medial aspect.

FIG. 424.—Plan of ossification of the fibula. From three centres.

upper and middle parts of the bone. It gives attachment to an aponeurosis which separates the Tibialis posterior from the Soleus and Flexor hallucis longus.

The anterior surface is the interval between the anterolateral and anteromedial borders. It is narrow and flat in the upper third of its extent; broader and grooved longitudinally in its lower third; it serves for the origin of the Extensor digitorum longus, Extensor hallucis longus, and Peroneus tertius.

The posterior surface is between the posterolateral and posteromedial borders; it is continuous below with the triangular area above the articular surface of the lateral malleolus, and is directed backwards above and medialwards below. Its upper third is rough for the origin of the Soleus; its lower part, triangular in shape, is connected to the tibia by a strong interosseous ligament; the intervening part is covered by the fibres of origin of the Flexor hallucis longus. Near the middle of this surface is the nutrient foramen, which is directed downwards.

The medial surface, between the anteromedial and posteromedial borders, is concave and gives origin to part of the Tibialis posterior.

The lateral surface is between the anterolateral and posterolateral borders.

Broad and often deeply grooved, it is directed lateralwards in its upper two-thirds, and backwards in its lower third, where it is continuous with the posterior border of the lateral malleolus. This surface gives origin to the *Peronæi longus* and *brevis*, and its lower part is covered by the tendons of these muscles.

The lower extremity, or lateral malleolus, is of a pyramidal form, and somewhat flattened from side to side; it descends to a lower level than the medial malleolus. The lateral surface is convex, and continuous with the triangular, subcutaneous surface on the lateral side of the body. The medial surface (fig. 423) presents in front a smooth triangular surface, convex from above downwards, which articulates with the lateral side of the talus. Behind and beneath the articular surface is a rough depression for the attachment of the posterior talofibular ligament. The anterior border is thick and rough, and marked below by a depression for the attachment of the anterior talofibular ligament. The posterior border is broad, and presents a shallow groove which is traversed by the tendons of the *Peronæi longus* and *brevis*. The summit is rounded, and gives attachment to the calcaneo-fibular ligament.

Ossification.—The fibula is ossified from three centres (fig. 424): one for the body, and one for either end. Ossification begins in the body about the eighth week of foetal life, in the lower end during the second year, and in the upper about the fourth year. The lower epiphysis, the first to ossify, unites with the body about the twentieth year; the upper about the twenty-fifth year.

Applied Anatomy.—In fractures of the bones of the leg, both bones are generally involved, but either bone may be broken separately, the fibula more frequently than the tibia. Fracture of both bones may be caused by either direct or indirect violence. When it occurs from indirect force, the fracture in the tibia is at the junction of the middle with the lower one-third of the bone. Many causes conduce to render this the weakest part of the bone. The fracture of the fibula is usually at a rather higher level. These fractures present great variety, both as regards their direction and condition. They may be oblique, transverse, longitudinal, or spiral. When oblique, they are for the most part the result of indirect violence, and the direction of the fracture is downwards, forwards, and medialwards in many cases, but may be downwards and lateralwards, or downwards and backwards. When transverse, the fracture is often at the upper part of the bone, and is the result of direct violence. The spiral fracture of the tibia generally starts as a vertical fissure, involving the ankle-joint, and is associated with fracture of the fibula higher up. It is the result of torsion, from twisting of the body while the foot is fixed.

Fractures of the tibia alone are almost always the result of direct violence, except where the malleolus is broken off by twists of the foot. Fractures of the fibula alone may arise from indirect or direct force, those of the lower end being usually the result of the former, and those higher up being caused by a direct blow on the part.

The tibia is the bone which is most commonly and most extensively distorted in rickets. It bends at the junction of the middle and lower third, its weakest part, and presents a curve forwards with generally some lateral displacement.

The tibia is more often the seat of acute infective necrosis than any other bone in the body, and with the formation of the sequestrum a large amount of new bony material is thrown out by the periosteum. The sequence of events in this disease can be very closely followed in the case of the tibia, and it is not uncommon to find a patient from whom the whole diaphysis of the tibia has been removed, going about with a new bone entirely of periosteal formation. Chronic bone abscess is more frequently met with in the cancellous tissue of the head or lower end of the tibia than in any other bone in the body. These abscesses are very chronic, and in most cases the result of tuberculous osteitis, although they are sometimes due to the organisms of suppuration or even the *bacillus typhosus*.

THE PATELLA

The patella (figs. 425 and 426), the largest of the sesamoid bones, is situated in front of the knee-joint in the tendon of the *Quadriceps femoris* muscle. It is flat and triangular, and has an anterior and a posterior surface, three borders, and an apex.

The anterior surface is convex, perforated by apertures for the passage of nutrient vessels, and marked by numerous rough, longitudinal striæ. It is separated from the integument by a bursa and is covered, in the recent state, by an expansion from the tendon of the *Quadriceps femoris*, which is continuous

below with the superficial fibres of the ligamentum patellæ. The *posterior surface* presents above a smooth, oval, articular area, divided into two facets by a vertical ridge; the ridge corresponds to the groove on the patellar surface of the femur, and the facets to the medial and lateral parts of the same surface; the lateral facet is the broader and deeper. Below the articular surface is a rough, convex, non-articular area, the lower part of which gives attachment to the ligamentum patellæ; the upper part is separated from the head of the tibia by fat.

FIG. 425.—Right patella.
Anterior surface.

FIG. 426.—Right patella.
Posterior surface.

The *base* or *superior border* is thick, and sloped from behind, downwards, and forwards: it gives attachment, except near its posterior margin, to that portion of the Quadriceps femoris which is derived from the Rectus femoris and Vastus intermedius. The *medial* and *lateral borders* are thinner and converge below: they give attachment to those portions of the Quadriceps femoris which are derived from the Vasti medialis and lateralis. Near the junction of the superior and lateral borders is a small shallow circular depression into which a part of the tendon of the Vastus lateralis is inserted.

The *apex* is pointed, and gives attachment to the ligamentum patellæ.

Structure. The patella consists of a nearly uniform dense spongy substance, covered by a thin compact lamina. The cancelli immediately beneath the anterior surface are arranged parallel with it. In the rest of the bone they radiate from the articular surface towards the other parts of the bone.

Ossification.—The patella is ossified from a single centre, which usually makes its appearance in the second or third year, but may be delayed until the sixth year. Ossification is completed about the age of puberty.

Applied Anatomy.—Fractures of the patella are of frequent occurrence. They are most often produced by muscular action—that is to say, by violent contraction of the Quadriceps femoris while the limb is in a position of semiflexion, so that the bone is snapped across the condyles of the femur and the fracture is transverse. Fracture of the patella is also produced by direct violence, such as falls on the knee, and here the fracture is usually stellate and the bone comminuted. Owing to the displacement of the fragments, and the difficulty there is in maintaining them in apposition, union takes place by fibrous tissue which may subsequently stretch, producing wide separation of the fragments and permanent lameness. Really satisfactory results after this fracture are generally only to be obtained by opening the joint and wiring the fragments together, and this is especially so when there is marked separation of the fragments owing to laceration of the retinacula.

If the fracture involve only the lower and non-articular part of the bone, it is an anatomical possibility for such to take place without injury to the synovial stratum and without involving the cavity of the knee-joint.

THE SKELETON OF THE FOOT

The skeleton of the foot (figs. 427 and 428) consists of three parts: the tarsus, metatarsus, and phalanges.

THE TARSUS

The tarsal bones (*ossa tarsi*) are seven in number: viz. the talus, calcaneus, navicular, first, second, and third cuneiforms, and the cuboid.

FIG. 427.—Bones of the right foot. Dorsal surface.

FIG. 428.—Bones of the right foot. Plantar surface.

THE TALUS (figs. 429 to 432)

The talus (astragalus), the second largest of the tarsal bones, supports the tibia and rests on the calcaneus; it articulates on either side with the

FIG. 429.—Left talus, from above.

FIG. 430.—Left talus, from below

malleoli and in front with the navicular bone. It consists of a head, neck, body, and trochlea.

The head is directed forwards and medialwards. Its anterior or navicular surface is oval and convex, with its long axis running downwards and medialwards; it articulates with the concavity of the navicular bone. On the inferior surface of the head are three articular areas. The largest and hindmost,

termed the *middle calcaneal surface*, articulates with the upper surface of the sustentaculum tali. Anterior and lateral to this surface, and as a rule continuous with it, is the *anterior calcaneal surface*, quadrilateral or irregularly oval in shape, for articulation with the anterior part of the upper surface of the calcaneus. Sometimes the anterior and middle calcaneal articular surfaces are partly or wholly discontinuous. Medial to the anterior calcaneal surface is a triangular, convex area, which extends on to the medial side of the head; it rests on the inferior calcaneonavicular ligament and on the anterior part of the deltoid ligament of the ankle-joint.

The *neck* is the constricted part connecting the head with the body. Its *superior* and *medial* surfaces are rough and perforated by vascular foramina.

FIG. 431.—Left talus, medial surface.

FIG. 432.—Left talus, lateral surface.

The superior surface gives attachment to the talonavicular ligament, and a depression on it, immediately in front of the superior surface of the trochlea, receives the anterior edge of the lower end of the tibia when the foot is flexed at the ankle-joint. The *lateral* surface is narrow, concave, and continuous with the *inferior* surface, which consists of the *sulcus tali*, a deep groove, wide in front and narrow behind, and directed forwards and lateralwards; in the articulated foot the sulcus tali overlies the sulcus calcanei and the two sulci form the *sinus tarsi*, a tunnel which is filled, in the recent condition, with the interosseous talocalcaneal ligament.

The *body* is the cuboidal posterior part of the bone, and from its upper surface the articular eminence termed the *trochlea* projects. The superior surface of the trochlea articulates with the lower end of the tibia; it is broader in front than behind, convex from before backwards, and slightly concave

from side to side. Its medial margin is straight, but its lateral is curved and inclines medialwards posteriorly where it usually expands into a small triangular facet * which comes into contact with the inferior transverse ligament of the ankle-joint during flexion of that articulation. The medial surface of the trochlea articulates with the medial malleolus: it is pear-shaped, with the blunt end directed forward. Below this surface is a rough, depressed area on the body for attachment of the deep part of the deltoid ligament of the ankle-joint. The lateral surface of the trochlea articulates with the lateral malleolus. It is concave vertically, triangular in outline with its apex downwards. Below the apex, the body projects as a rough, triangular eminence, named the *lateral process*; to it the lateral talocalcaneal ligament is attached. In front of the articular surface for the lateral malleolus is a rough impression for the anterior

FIG. 433.—Left calcaneus, superior surface.

FIG. 434.—Left calcaneus, inferior surface.

talofibular ligament, while below and behind it is a groove in which a part of the posterior talofibular ligament is implanted.

On the *inferior* surface of the body is the *posterior calcaneal surface*, which is large in size and oval in form for articulation with the upper surface of the calcaneus. It is limited in front by the sulcus tali and is deeply concave in the direction of its long axis, which runs forwards and lateralwards at an angle of about 45° with the median plane.†

The *posterior* surface of the body is small, and projects backwards as the *posterior process*; it is traversed in a direction downwards and medialwards by a sulcus for the tendon of the Flexor hallucis longus. On either side of this sulcus is a tubercle. That on the lateral side is the more prominent and gives attachment to the main part of the posterior talofibular ligament; it is sometimes detached from the rest of the bone, and is then known as the *os trigonum*. To the smaller medial tubercle the medial talocalcaneal ligament is attached.

* Fawcett, *Edinburgh Medical Journal*, 1895.

† Sewell (*Journal of Anatomy and Physiology*, vol. xxxviii.) pointed out that in about 10 per cent. of bones a small triangular facet, continuous with the posterior calcaneal facet, is present at the junction of the lateral surface of the body with the posterior wall of the sulcus tali.

THE CALCANEUS (figs. 433 to 436)

The **calcaneus** (os calcis) is the largest of the tarsal bones. It is situated at the lower and back part of the foot, serving to transmit the weight of the body to the ground, and forming a strong lever for the muscles of the calf. It is irregularly cuboidal in form, having its long axis directed forwards and lateralwards.

The *superior surface* (fig. 433) consists of a posterior non-articular and an anterior articular part. The former varies in length in different individuals, is convex from side to side, concave from before backwards, and supports a

FIG. 435.—Left calcaneus, lateral surface.

FIG. 436.—Left calcaneus, medial surface.

mass of fat placed in front of the tendo calcaneus. In front of this area is the *posterior articular surface*, a large, usually somewhat oval-shaped facet, which looks upwards and forwards: it is convex from behind forwards, and articulates with the posterior calcaneal facet on the under surface of the talus. It is bounded anteriorly by a deep depression which is continued backwards and medialwards in the form of a groove, the *sulcus calcanei*; in the articulated foot this sulcus lies below the sulcus tali, and the two sulci form a tunnel (*sinus tarsi*) for the lodgment of the interosseous talocalcaneal ligament. In front and to the medial side of this sulcus is an elongated facet, concave from behind forwards, and with its long axis directed forwards and lateralwards. This facet is frequently divided into two parts: of these, the posterior and larger is termed the *middle articular surface*; it is supported on a projecting process of bone, the *sustentaculum tali*, and articulates with the middle calcaneal facet on the under surface of the talus; the anterior and lesser, termed the

anterior articular surface, is placed on the anterior part of the body, and articulates with the anterior calcaneal facet on the under surface of the talus. The upper surface, anterior and lateral to the facets, is rough for the attachment of ligaments and for the origin of the *Extensor digitorum brevis*.

The *inferior or plantar surface* (fig. 434) is uneven, wider behind than in front, and convex from side to side; it is bounded posteriorly by the lower part of the calcaneal tuberosity, which presents a medial and a lateral process; the *lateral process*, small, prominent, and rounded, gives origin to part of the *Abductor digiti quinti*; the *medial process*, broader and larger, gives attachment, by its prominent medial margin, to the *Abductor hallucis*, and in front to the plantar aponeurosis and the *Flexor digitorum brevis*; the depression between the processes gives origin to the *Abductor digiti quinti*. The rough surface in front of the processes gives attachment to the long plantar ligament, and the lateral head of the *Quadratus plantæ*; to a prominent tubercle near the anterior part of this surface and to a transverse groove in front of the tubercle, the plantar calcaneocuboid ligament is attached.

The *lateral surface* (fig. 435) is broad behind, and narrow in front, flat and almost subcutaneous; near its centre is a small tubercle, for the attachment of the calcaneofibular ligament. Below and in front of this tubercle is a ridge, the *trochlear process* (peroneal tubercle), which is often indistinctly marked. It gives attachment to the inferior peroneal retinaculum, and separates two grooves; the superior groove transmits the tendon of the *Peronæus brevis*; the inferior, that of the *Peronæus longus*.

The *medial surface* (fig. 436) is directed obliquely downwards and forwards, and is deeply concave; above the anterior part of the concavity is a horizontal eminence, the *sustentaculum tali*. The superior surface of this eminence is concave, and articulates with the middle calcaneal articular surface of the talus; its inferior surface is grooved for the tendon of the *Flexor hallucis longus*; its anterior margin gives attachment to the plantar calcaneonavicular ligament, and its medial margin to a part of the deltoid ligament of the ankle joint.

The *anterior extremity or cuboid articular surface* is of a somewhat triangular form. It is concave from above downwards and lateralwards, and convex in a direction at right angles to this. Its medial border gives attachment to the plantar calcaneonavicular ligament.

The *posterior extremity or calcaneal tuberosity* is prominent, convex, wider below than above, and divisible into three areas. The lowest of these is rough, and covered by the fatty and fibrous tissue of the heel; the middle, also rough, gives insertion to the tendo calcaneus and *Plantaris*; while the highest is smooth, and is covered by a bursa which intervenes between this part of the tuberosity and the tendo calcaneus. The plantar surface of this tuberosity displays the medial and lateral processes already described.

THE NAVICULAR BONE (OS NAVICULARE PEDIS)

The *navicular bone* (fig. 437) is situated at the medial side of the tarsus, between the talus behind and the cuneiform bones in front.

FIG. 437.—The left navicular bone. A. Anterolateral view. B. Posteromedial view.

The *anterior surface* is convex from side to side, and subdivided by two ridges into three facets, for articulation with the three cuneiform bones. The

posterior surface, oval and concave, articulates with the rounded head of the talus. The *dorsal surface* is convex from side to side, and rough for the attachment of ligaments. The *plantar surface*, irregularly concave, displays on its lateral part a downward projection of varying size, the *plantar process*, to which a portion of the plantar calcaneonavicular ligament is attached. The *medial surface* consists of a rounded *tuberosity*, the lower part of which gives insertion to a large part of the tendon of the Tibialis posterior. Between the tuberosity and the plantar process is a well-marked groove for the lodgment of a part of the tendon of the Tibialis posterior. The *lateral surface* is rough and irregular for the attachment of ligaments, and frequently presents a facet for articulation with the cuboid bone.

THE CUNEIFORM BONES

The **cuneiform bones**, three wedge-shaped bones, articulate with the navicular bone behind and with the first, second, and third metatarsal bones in front; the first cuneiform bone is the largest, and the second the smallest.

FIG. 438.—The left first cuneiform bone.

In the articulated foot the posterior surfaces of the three cuneiform bones form a slight concavity for the navicular, but the anterior portions of the first and third project in front of the anterior surface of the second and form with it a deep recess in which the base of the second metatarsal bone is lodged.

The **first cuneiform bone** (*os cuneiforme primum*) (fig. 438), the largest, is situated at the medial side of the foot, between the navicular bone behind and the base of the first metatarsal bone in front and has the thin end of the wedge directed upwards.

The *medial surface* is subcutaneous, broad and quadrilateral; at its anterior plantar angle is a smooth oval impression, into which a part of the tendon of the Tibialis anterior is inserted. The *lateral surface* is concave; along its superior and posterior borders is a narrow L-shaped surface, the vertical limb and posterior part of the horizontal limb of which articulate with the second cuneiform bone, while the anterior part of the horizontal limb articulates with the second metatarsal bone; the facet for the second metatarsal bone is occasionally separated by a groove from that for the second cuneiform bone. The rest of this surface is rough for the attachment of ligaments and part of the tendon of the Peronæus longus. The *anterior surface*, large and kidney-shaped, articulates with the base of the first metatarsal bone. The *posterior surface*, triangular and concave, articulates with the medial facet on the anterior surface of the navicular bone. The *plantar surface* forms the base of the wedge; at its posterior part is a tuberosity for the insertion of part of the tendon of the Tibialis posterior; in front of this a part of the tendon of the Tibialis anterior is inserted. The *dorsal surface* is the thin end of the wedge, and is directed upwards and lateralwards; it is rough for the attachment of ligaments.

The **second cuneiform bone** (*os cuneiforme secundum*) (fig. 439), the smallest, is of very regular wedge-like form, the thin end being directed down-

wards. It is situated between the first and third cuneiform bones, and articulates with the navicular bone behind, and the second metatarsal bone in front.

The *anterior surface*, triangular in form, articulates with the base of the second metatarsal bone. The *posterior surface*, also triangular, articulates with the intermediate facet on the anterior surface of the navicular bone. On the *medial surface* is an L-shaped facet, running along the superior and posterior borders, for articulation with the first cuneiform bone; the rest of the surface is rough for the attachment of ligaments. The *lateral surface*

For 2nd metatarsal bone

For navicular bone

For 3rd cuneiform bone

presents posteriorly a smooth facet for articulation with the third cuneiform bone. The *dorsal surface* or base of the wedge is quadrilateral and rough for the attachment of ligaments. The *plantar surface*, sharp and tuberculated, is also rough for the attachment of ligaments, and for the insertion of a slip from the tendon of the *Tibialis posterior*.

The **third cuneiform bone** (*os cuneiforme tertium*) (fig. 440), is intermediate in size between the first and second, and its base is directed upwards. It is placed between the second cuneiform and cuboid bones, and articulates with the navicular bone behind, and the third metatarsal bone in front.

The *anterior surface*, triangular in form, articulates with the base of the third metatarsal bone. The *posterior surface* articulates with the lateral facet on the anterior surface of the navicular bone, and is rough below for the attachment of ligamentous fibres. The *medial surface* presents an anterior and a posterior

articular facet: the anterior, sometimes divided, articulates with the lateral side of the base of the second metatarsal bone; the posterior skirts the posterior border, and articulates with the second cuneiform bone; the intervening rough area gives attachment to an interosseous ligament. The *lateral surface* also presents two articular facets; the anterior one, situated at the superior angle of the bone, is small and semi-oval in shape, and articulates with the medial side of the base of the fourth metatarsal bone; the posterior and larger one is triangular or oval, and articulates with the cuboid bone; the intervening, rough, non-articular area serves for the attachment of an interosseous ligament. The *dorsal surface* is of an oblong form, its posterolateral angle being prolonged backwards. The *plantar surface* is a rounded margin, and serves for

the attachment of ligaments and parts of the tendons of the *Tibialis posterior* and *Flexor hallucis brevis*.

THE CUBOID BONE (OS CUBOIDEUM)

The cuboid bone (fig. 441) is placed on the lateral side of the foot, in front of the calcaneus, and behind the fourth and fifth metatarsal bones.

The *dorsal surface*, directed upwards and lateralwards, is rough for the attachment of ligaments. The *plantar surface* is crossed in front by a deep groove, the *peronæal sulcus*, which runs obliquely forwards and medialwards; it lodges the tendon of the *Peronæus longus*, and is bounded behind by a prominent ridge, to which the long plantar ligament is attached. The ridge ends laterally in the *tuberosity*, the lateral part of which presents an oval facet: on this facet the sesamoid bone or cartilage which is frequently found in the tendon of the *Peronæus longus* glides. Behind the peronæal sulcus the bone is rough, for the attachment of the plantar calcaneocuboid ligament, a few fibres of the *Flexor hallucis brevis*, and a fasciculus from the tendon of the *Tibialis*.

FIG. 441.—The left cuboid bone. A. Antromedial view. B. Posterolateral view.

posterior. On the *lateral surface* is a deep notch formed by the commencement of the peronæal sulcus. The *posterior surface* is smooth, triangular, and concavoconvex, for articulation with the anterior surface of the calcaneus; its inferior, medial angle projects backwards as a process which underlies and supports the anterior end of the calcaneus. The *anterior surface* is divided by a vertical ridge into two facets; the medial, quadrilateral in form, articulates with the fourth metatarsal bone; the lateral, triangular, with the fifth. The *medial surface* is irregularly quadrilateral, and at its middle and upper part is a smooth oval facet, for articulation with the third cuneiform bone; behind this a small facet for articulation with the navicular bone is frequently present; the rest of this surface is rough for the attachment of interosseous ligaments.

THE METATARSUS

The *metatarsus* consists of five bones which are numbered from the medial side (ossa metatarsalia I-V); each has a body, a tarsal end or base, and a phalangeal end or head.

COMMON CHARACTERISTICS OF THE METATARSAL BONES

The *body* is prismoid in form; it tapers gradually from the base to the head, and is slightly convex longitudinally on its dorsal aspect. The *base* articulates proximally with the tarsus, and by its sides with the contiguous metatarsal bones. The *head* has a convex articular surface, which extends farther backwards below than above. Its sides are flattened, and on each is a depression, surmounted by a tubercle, for ligamentous attachment. Its *plantar surface* is marked on either side by an articular eminence continuous with the terminal articular surface.

CHARACTERISTICS OF THE INDIVIDUAL METATARSAL BONES

The first metatarsal bone (fig. 442) is the shortest and thickest of the metatarsal bones. The *body* is strong, and of well-marked prismoid form.

FIG. 442.—The first left metatarsal bone.

FIG. 443.—The second left metatarsal bone.

FIG. 444.—The third left metatarsal bone.

FIG. 445.—The fourth left metatarsal bone.

The *base* has, as a rule, no articular facets on its sides, but there is occasionally one on the lateral side for articulation with the second metatarsal bone. Its proximal articular surface, of large size and kidney-shaped, articulates with the

first cuneiform bone; its circumference is grooved, for the tarsometatarsal ligaments, and medially gives insertion to part of the tendon of the *Tibialis anterior*; its plantar angle presents a rough oval prominence for the insertion of the tendon of the *Peronæus longus*. The *head* is large; on its plantar surface is a median elevation separating two grooved facets, on which sesamoid bones glide.

The **second metatarsal bone** (fig. 443) is the longest of the metatarsal bones. On its wedge-shaped *base* are four articular facets: one on its proximal surface, of a triangular form, for articulation with the second cuneiform bone; one at the upper part of its medial surface, for articulation with the first cuneiform bone; and two on its lateral surface, an upper and lower, separated by a rough non-articular interval. Each of these lateral articular surfaces is divided by a vertical ridge; the two anterior facets articulate with the third metatarsal bone; the two posterior (sometimes continuous) with the third cuneiform bone. A fifth facet is occasionally present for articulation with the first metatarsal bone; it is oval in shape, and is situated on the medial side of the base, distal to the facet for the first cuneiform bone.

The **third metatarsal bone** (fig. 444) has a triangular *base* which articulates proximally with the third cuneiform bone, medially it articulates by two facets with the second metatarsal bone; and laterally by a single facet, situated at the dorsal angle, with the fourth metatarsal bone.

FIG. 446.—The fifth left metatarsal bone.

The **fourth metatarsal bone** (fig. 445) is smaller than the third. Its *base* presents an oblique quadrilateral facet on its proximal surface for articulation with the cuboid bone; on the lateral side a single facet, for the fifth metatarsal bone; on the medial side a facet divided by a ridge into an anterior portion for the third metatarsal bone, and a posterior portion for the third cuneiform bone.

The **fifth metatarsal bone** (fig. 446) is recognised by a rough eminence, the *tuberosity*, on the lateral side of its base. The *base* articulates proximally, by a triangular, obliquely cut surface, with the cuboid bone; and medially, with the fourth metatarsal bone. On the medial part of its dorsal surface is inserted the tendon of the *Peronæus tertius*, and on the dorsal surface of the *tuberosity* that of the *Peronæus brevis*. A strong band of the plantar aponeurosis connects the projecting part of the *tuberosity* with the lateral process of the *tuberosity* of the calcaneus. The plantar surface of the base is grooved for the tendon of the *Abductor digiti quinti*, and gives origin to the *Flexor digiti quinti brevis*.

THE PHALANXES (PHALANXES DIGITORUM PEDIS)

The **phalanges** of the foot correspond in number and general arrangement with those of the hand: there are two in the great toe, and three in each of the other toes. They are, however, much smaller, and their bodies, especially those of the bones of the first row, are laterally compressed.

The phalanges of the **first row** closely resemble those of the hand. The *body* of each is compressed from side to side, convex above, concave below. The *base* is concave; and the *head* presents a trochlear surface for articulation with the second phalanx.

The phalanges of the **second row** are remarkably small and short, but rather broader than those of the first row.

The **ungual phalanges** resemble those of the fingers; but they are smaller and are flattened from above downwards; each presents a broad base for

articulation with the corresponding bone of the second row, and an expanded distal extremity for the support of the nail and the end of the toe.

OSSIFICATION OF THE BONES OF THE FOOT (fig. 447)

The **tarsal bones** are each ossified from a single centre, excepting the calcaneus, which has an epiphysis for its tuberosity. The centres make their appearance in the following order: calcaneus, at the sixth month of foetal life; talus, about the seventh month; cuboid, at the ninth month; third cuneiform, during the first year; first cuneiform, in the third year; second cuneiform and navicular, in the

FIG. 447.—Plan of ossification of the foot.

fourth year. The epiphysis for the tuberosity of the calcaneus begins to ossify between the sixth and tenth years, and unites with the rest of the bone soon after puberty. The lateral tubercle of the posterior process of the talus is sometimes ossified from an independent centre, and may remain separate from the rest of the bone, when it is named the *os trigonum*.

The **metatarsal bones** are each ossified from two centres: a primary centre for the body, and an epiphysal centre for the proximal end of the first, and for the distal end of each of the other four.* Ossification commences in the body about the eighth or ninth week of foetal life. The epiphysis for the base of the

* As in the first metacarpal (see footnote, page 297), so in the first metatarsal, there is often a second epiphysis for the head.

first metatarsal appears about the third year; those for the heads of the other metatarsals between the third and fourth years; all join the bodies between the seventeenth and twentieth years.

The **phalanges** are each ossified from two centres: a primary one for the body and an epiphysis for the base. The primary centres for the ungual phalanges appear about the eighth week of foetal life; those for the first phalanges between the twelfth and sixteenth weeks, and those for the second phalanges after the sixteenth week (that for the second phalanx of the fifth toe does not usually appear until after birth). The epiphysial centres appear between the third and sixth years, and unite with the bodies about the seventeenth or eighteenth year.

COMPARISON OF THE BONES OF THE HAND AND FOOT

The hand and foot are constructed on somewhat similar principles, each consisting of a proximal part, the carpus (or tarsus), a middle portion, the metacarpus (or metatarsus), and a terminal portion, the phalanges. The proximal part consists of a series of more or less cubical bones which allow a slight amount of

FIG. 448.—Skeleton of foot. Medial aspect.

FIG. 449.—Skeleton of foot. Lateral aspect

gliding on one another and are chiefly concerned in distributing forces transmitted to or from the bones of the arm or leg. The middle part is made up of slightly movable long bones which assist the carpus or tarsus in distributing forces and also give greater breadth for the reception of such forces. The separation of the individual bones from one another allows of the attachments of the interosseous muscles and protects the dorsopalmar and dorsiplantar vascular anastomoses. The terminal portion is the most movable, and its separate elements enjoy a varied range of movements, the chief of which are flexion and extension.

The functions of the hand and foot are, however, very different, and the general similarity between them is greatly modified to meet these requirements. Thus the foot forms a firm basis of support for the body in the erect posture, and is therefore more solidly built, and its component parts are less movable on each other than

those of the hand. In the case of the phalanges the difference is readily noticeable; those of the foot are smaller and their movements more limited than those of the hand. Very much more marked is the difference between the metacarpal bone of the thumb and the metatarsal bone of the great toe. The metacarpal bone of the thumb is constructed to permit of great mobility; it is directed at an acute angle from that of the index finger, and is capable of a considerable range of movement at its articulation with the carpus. The metatarsal bone of the great toe assists in supporting the weight of the body, is constructed with great solidity, lies parallel with the other metatarsals, and has a very limited degree of mobility. The carpus is small in proportion to the rest of the hand, is placed in line with the forearm, and forms a transverse arch, the concavity of which constitutes a bed for the flexor tendons. The tarsus forms a considerable part of the foot, and is placed at right angles to the leg, a position which is almost peculiar to man, and has relation to his erect posture. In order to allow of their supporting the weight of the body with the least expenditure of material the tarsus and a part of the metatarsus are constructed in a series of arches (figs. 448 and 449), the disposition of which will be considered after the articulations of the foot have been described.

Applied Anatomy.—Considering the injuries to which the foot is subjected, it is surprising how seldom the tarsal bones are fractured. This is no doubt due to the fact that the tarsus is composed of a number of bones, articulated by a considerable extent of surface, and joined together by very strong ligaments which serve to break the force of violence applied to this part of the body. When fracture does occur, these bones being composed for the most part of a soft cancellous structure, covered only by a thin shell of compact tissue, are often extensively comminuted, especially as most of the fractures are produced by direct violence; and, as there is only a very scanty amount of soft parts over the bones, the fractures are very often compound, and amputation is often necessary.

When fracture occurs in the anterior group of tarsal bones, it is almost invariably the result of direct violence; but fractures of the posterior group—that is, of the calcaneus and talus—are usually produced by falls from a height on to the feet.

In club-foot (talipes), especially in congenital cases, the bones of the tarsus become altered in shape and size, and displaced from their proper positions. This is principally the case in congenital talipes equinovarus, in which the head of the talus becomes twisted and atrophied, and a similar condition may be present in the other bones, more especially the navicular. The tarsal bones are peculiarly liable to become the seat of tuberculous caries following comparatively trivial injuries, especially as they are not maintained in a condition of rest to the same extent as some other parts of the body after similar injuries. Caries of the calcaneus or talus may remain limited to the one bone for a long period, but when one of the other bones is affected, the remainder frequently become involved, since the disease spreads through the large and complicated synovial stratum which is more or less common to these bones.

Amputation of the foot is often required either for injury or disease. The principal amputations are as follows: (1) Syme's: amputation at the ankle-joint by a heel-flap, with removal of the malleoli and sometimes a thin slice from the lower end of the tibia. (2) Pirogoff's: amputation of the whole of the tarsal bones (except the posterior part of the calcaneus), and a thin slice from the tibia and fibula including the two malleoli. The sawn surface of the calcaneus is then turned up and united to the cut surface of the tibia. (3) Subastragalar: amputation of the foot below the talus through the joint between it and the calcaneus.

The bones of the tarsus occasionally require removal individually. This is especially the case with the talus for tuberculous disease limited to that bone; or the talus may require excision in cases of subastragalar dislocation, or in cases of inveterate talipes. The cuboid has been removed for the same reason.

Fractures of the metatarsal bones and phalanges are nearly always the result of direct violence, and in the majority of cases the injury is caused by severe crushing accidents, necessitating amputation. The metatarsal bones, and especially that of the great toe, are frequently diseased, either in tuberculous subjects or in patients with perforating ulcer of the foot.

SESAMOID BONES

Sesamoid bones are small more or less rounded masses of bone embedded in certain tendons and usually related to joint-surfaces. Their functions probably are to modify pressure, to diminish friction, and occasionally to alter the direction of the pull of a muscle. That they are not developed to meet certain physical requirements in the adult is evidenced by the fact that they are present as cartilaginous nodules in the foetus, and in greater numbers than in the adult. They must be regarded, according to Thilenius, as integral parts

of the skeleton phylogenetically inherited.* Physical necessities probably come into play in selecting and in regulating the degree of development of the original cartilaginous nodules.

Sesamoid bones are invested by the fibrous tissue of the tendons, except on the surfaces in contact with the parts over which they glide, where they present smooth articular facets.

In the upper extremity the sesamoid bones of the joints are found only on the palmar surface of the hand. Two, of which the medial is the larger, are constantly present at the metacarpophalangeal joint of the thumb; one is frequently present in the corresponding joint of the little finger, and one (or two) in the same joint of the index finger. Sesamoid bones are found occasionally at the metacarpophalangeal joints of the middle and ring fingers, at the interphalangeal joint of the thumb, and at the distal interphalangeal joint of the index finger.

In the lower extremity the largest sesamoid bone of the joints is the patella, developed in the tendon of the Quadriceps femoris. On the plantar aspect of the foot, two, of which the medial is the larger, are always present at the metatarsophalangeal joint of the great toe; one sometimes at the metatarsophalangeal joints of the second and fifth toes, one occasionally at the corresponding joints of the third and fourth toes, and one at the interphalangeal joint of the great toe.

Sesamoid bones apart from joints are seldom found in the tendons of the upper limb; one is sometimes seen in the tendon of the Biceps brachii opposite the radial tuberosity. They are, however, present in several of the tendons of the lower limb—viz. one in the tendon of the Peronæus longus, where it glides on the cuboid; one, appearing late in life, in the tendon of the Tibialis anterior, opposite the smooth facet of the first cuneiform bone; one in the tendon of the Tibialis posterior, opposite the medial side of the head of the talus; one in the lateral head of the Gastrocnemius, behind the lateral condyle of the femur; and one in the tendon of the Psoas major, where it glides over the os pubis. Sesamoid bones are found occasionally in the tendons which wind round the medial and lateral malleoli: one is sometimes present in the tendon of the Glutæus maximus where it passes over the greater trochanter.

* *Morpholog. Arbeiten*, v. 1906.

SYNDESMOLOGY

THE bones of the skeleton are connected to one another at different parts of their surfaces, and such connexions are termed *joints* or *articulations*. Where the joints are *immovable*, as in the articulations of the cranium, the opposed margins of the bones are nearly in contact, being separated merely by a thin layer of fibrous membrane, named the *sutural ligament*; in certain regions at the base of the skull this fibrous membrane is replaced by a layer of cartilage. Where *slight movement* combined with great strength is required, the opposed osseous surfaces are united by tough and elastic *fibrocartilages*, as in the joints between the vertebral bodies, and in the interpubic articulation. In the *freely movable* joints the opposed surfaces are completely separated from one another; the parts of the bones forming the articulations are expanded for greater convenience of mutual connexion, and are covered by hyaline cartilage, while the joints are enveloped by *articular capsules*, and are usually strengthened by strong fibrous bands called *ligaments*.

The extremities of the long bones are the parts which form the articulations; they are somewhat enlarged, and consist of spongy substance with a thin coating of compact substance. In the flat bones the articulations usually take place at the edges, and in the short bones at various parts of their surfaces. The layer of compact bone which forms the joint surface, and to which the articular cartilage is attached, is called the *articular lamella*; its lacunæ are large, but it contains no Haversian canals or canaliculi. The vessels of the spongy substance approach the articular lamella but do not perforate it; this lamella is consequently denser and firmer than ordinary bone.

Articular cartilage, which covers the articular surfaces of bones, and *fibrocartilage*, which enters into the structure of some of the joints, are described in the section on Histology (pp. 14 to 16).

Ligaments are composed mainly of parallel or closely interlaced bundles of *white fibrous tissue*, and present a silvery appearance. They are pliant and flexible, so as to allow perfect freedom of movement, but strong, tough, and inextensible, so as not to yield readily to applied force. Some ligaments consist entirely of *yellow elastic tissue*, as the *ligamenta flava* which connect together the laminae of adjacent vertebrae, and the *ligamentum nuchæ* in the lower animals. In these cases the elasticity of the ligament is intended to act as a substitute for muscular power.

The *articular capsules* form complete envelopes for the freely movable joints. Each capsule consists of two strata—an external (*stratum fibrosum*) composed of white fibrous tissue, and an internal (*stratum synoviale*) which secretes a lubricating fluid, and is sometimes described separately as the *synovial membrane*.

The *stratum fibrosum* is attached to the circumferences of the articular ends of the bones entering into the joint, and thus entirely surrounds the articulation.

The *stratum synoviale* invests the inner surface of the *stratum fibrosum*, is reflected over any tendons passing through the joint-cavity, and ceases at the margins of the articular cartilages. It is composed of a thin, delicate, connective tissue, and is covered on its free surface by a layer of endothelium. In some joints it is thrown into folds which pass across the cavity, as in the knee-joint; in others there are flattened folds, subdivided at their margins into fringe-like processes which contain convoluted vessels. These folds

generally project near the margin of the cartilage, and lie flat upon its surface. The stratum synoviale secretes a small quantity of thick, viscid fluid, termed *synovia*.

Closely related in structure and function to the synovial stratum of the articular capsule, and therefore conveniently described in this section, are the *vaginæ mucosæ* of tendons and the *bursæ mucosæ*.

Vaginæ mucosæ or mucous sheaths serve to facilitate the gliding of tendons in fibro-osseous canals, e.g. the tendons of the flexor and extensor muscles of the fingers and toes as they pass through fibro-osseous canals in or near the hand and foot. Each sheath is arranged in the form of an elongated closed sac, one layer of which adheres to the wall of the canal, and the other is reflected upon the surface of the enclosed tendon.

Bursæ mucosæ are interposed between surfaces which glide upon each other. They consist of closed sacs containing a minute quantity of clear viscid fluid, and may be grouped, according to their situations, under the headings *subcutaneous*, *submuscular*, *subfascial*, and *subtendinous*.

CLASSIFICATION OF JOINTS

Joints are divided into three classes: *synarthroses* or immovable, *amphiarthroses* or slightly movable, and *diarthroses* or freely movable.

1. SYNARTHROSES. (IMMOVABLE ARTICULATIONS)

Synarthroses are articulations in which the surfaces of the bones are fastened together by intervening connective tissue or hyaline cartilage, and in which there is no appreciable motion, as in the joints between the bones of the cranium. There are three varieties of synarthrosis: *sutura*, *gomphosis*, and *synchondrosis*.

Sutura is an articulation met with only in the skull, where the margins of the bones articulate with one another (fig. 450). The margins of the bones are not in direct contact, being separated by a thin layer of fibrous tissue, continuous externally with the *periosteum*, internally with the *dura mater*.

FIG. 450.—Section across the sagittal suture.

FIG. 451.—Section through occipitosphenoïdal synchondrosis of an infant.

When the bony margins are connected by a series of interlocking, tooth-like processes, the articulation is named a *sutura serrata*, as in the sagittal suture. When the articulation is formed by one bone overlapping another, as in the suture between the temporal and parietal bones, it is termed a *sutura squamosa*; where there is simple apposition of contiguous rough surfaces, as between the maxillæ, or the horizontal parts of the palatine bones, it is named a *sutura harmonia*.

Gomphosis is articulation by the insertion of a conical process into a socket; it is seen in the articulations of the roots of the teeth with the alveoli of the mandible and maxillæ.

Synchondrosis.—Where the connecting medium is cartilage the joint is termed a *synchondrosis* (fig. 451); this is a temporary form of joint, for the cartilage is ultimately converted into bone. Such joints are found between the epiphyses and bodies of long bones, between the occipital and the sphenoidal bone at and for some years after birth, and between the petrous portion of the temporal bone and the jugular process of the occipital bone.

2. AMPHIARTHROSES. (SLIGHTLY MOVABLE ARTICULATIONS)

In these articulations the contiguous bony surfaces are either united by an interosseous ligament, as in the inferior tibiofibular articulation, or are covered by articular cartilage and connected by broad flattened discs of fibrocartilage, of a more or less complex structure, as in the articulations between the bodies of the vertebræ. The first form is termed a **syndesmosis** the second a **symphysis** (fig. 452).

3. DIARTHROSES. (FREELY MOVABLE ARTICULATIONS)

This class includes the majority of the joints. In a diarthrodial joint the contiguous bony surfaces are covered with articular cartilage, and connected by an articular capsule and ligaments (*articulatio simplex*) (fig. 453). The joint may be divided, completely or incompletely, by an *articular disc*

FIG. 452.—Diagrammatic section of a symphysis.

FIG. 453.—Diagrammatic section of a simple diarthrodial joint.

FIG. 454.—Diagrammatic section of a diarthrodial joint with an articular disc.

or *meniscus*, the periphery of which is continuous with the fibrous stratum of the articular capsule while its free surfaces are covered by the synovial stratum (*articulatio composita*) (fig. 454).

Joints of this class are subdivided according to the kind of motion permitted in them. There are two varieties in which the movement is uni-axial; that is to say, all movements take place around one axis. In one, the *ginglymus* or *hinge-joint*, this axis is, practically speaking, transverse; in the other, the *articulatio trochoidea* or *pivot-joint*, it is longitudinal. There are two varieties where the movement is bi-axial; these are the *articulatio ellipsoidea* or *condyloid joint* and the *articulatio sellaris* or *saddle-joint*. There is one form where the movement is poly-axial, the *articulatio sphaeroidea* or *enarthrosis* (*ball-and-socket joint*); and finally there is the *arthrodia* or *gliding joint*.

Ginglymus or hinge-joint.—In this form the articular surfaces are moulded to each other in such a manner as to permit motion only in one plane. The articular surfaces are connected together by strong collateral ligaments, which form their chief bond of union. The best examples of ginglymus are the interphalangeal joints and the joint between the humerus and ulna.

Trochoid articulation or pivot-joint.—Where the movement is limited to rotation, the joint is formed by a pivot-like process turning within a ring, or a

ring on a pivot, the ring being formed partly of bone, partly of ligament. In the proximal radio-ulnar articulation, the ring is formed by the radial notch of the ulna and the annular ligament; here, the head of the radius rotates within the ring. In the articulation of the dens of the epistropheus with the atlas, the ring is formed in front by the anterior arch, and behind by the transverse ligament, of the atlas; here, the ring rotates round the dens.

Condylod articulation.—In this form of joint, an ovoid articular surface, or condyle, is received into an elliptical cavity in such a manner as to permit of flexion, extension, adduction, abduction, and circumduction, but no axial rotation. The radiocarpal joint is an example of this form of articulation.

Saddle-articulation.—In this variety the opposing surfaces are reciprocally concavoconvex, and the movements are the same as in the preceding form. The best example of the saddle-articulation is the carpometacarpal joint of the thumb.

Enarthrosis is a joint in which the distal bone is capable of motion around an indefinite number of axes, which have one common centre. It is formed by the reception of a globular head into a cup-like cavity, hence the name 'ball-and-socket.' Examples of this form of articulation are found in the hip- and shoulder-joints.

Arthrodia is a joint which admits of only gliding movement; it is formed by the apposition of plane, or nearly plane, surfaces, the amount of motion in such joints being limited by the ligaments or osseous processes surrounding the articulations. It is the form present in the joints between the articular processes of the vertebræ, and in most of the carpal and tarsal joints.

THE KINDS OF MOVEMENT PERMITTED IN JOINTS

The movements permitted in joints may be divided into four kinds: gliding and angular movements, circumduction, and rotation. Frequently these are more or less combined in the various joints, so as to produce an infinite variety, and it is seldom that only one kind of motion is found in any particular joint.

Gliding movement is the simplest kind of motion that can take place in a joint, one surface gliding over another without any angular or rotatory movement. It is common to all movable joints; but in some, as in most of the articulations of the carpus and tarsus, it is the only motion permitted. This movement is not confined to plane surfaces, but may take place between any two contiguous surfaces, of whatever form.

Angular movement occurs only between the long bones, and by it the angle between the two bones is increased or diminished. It may take place: (1) forwards and backwards, constituting flexion and extension; or (2) towards and from the median plane of the body, or, in the case of the fingers or toes, from the middle line of the hand or foot, constituting adduction and abduction. The strictly ginglymoid or hinge-joints admit of flexion and extension only. Abduction and adduction, combined with flexion and extension, are met with in the more movable joints.

Circumduction is that form of motion which takes place between the head of a bone and its articular cavity, when the bone is made to circumscribe a conical space; the base of the cone is described by the distal end of the bone, the apex is in the articular cavity; this kind of motion is best seen in the shoulder- and hip-joints.

Rotation is a form of movement in which a bone moves round a longitudinal axis; the axis of rotation may lie in a separate bone, as in the case of the pivot formed by the dens of the epistropheus around which the atlas turns; or a bone may rotate around its own longitudinal axis, as in the rotation of the humerus at the shoulder-joint; or the axis of rotation may not be quite parallel to the long axis of the bone, as in the movement of the radius on the ulna during pronation and supination of the hand, where it is represented by a line connecting the centre of the head of the radius with the centre of the head of the ulna.

Ligamentous action of muscles.—The movements of the different joints of a limb are combined by means of the long muscles passing over more than one joint. These muscles, when relaxed and stretched to their greatest extent, act as elastic ligaments in restraining certain movements of one joint, except when combined with

corresponding movements of the other—the latter movements being usually in the opposite direction. Thus the shortness of the hamstring muscles prevents complete flexion of the hip, unless the knee-joint is also flexed so as to bring their attachments nearer together. The uses of this arrangement are threefold. 1. It co-ordinates the kinds of movements which are the most habitual and necessary, and enables them to be performed with the least expenditure of power. 2. It enables the short muscles which pass over only one joint to act upon more than one. 3. It provides the joints with ligaments which, while they are of very great power in resisting movements to an extent incompatible with the mechanism of the joint, at the same time spontaneously yield when necessary.

Applied Anatomy.—W. W. Keen points out how important it is 'that the surgeon should remember this ligamentous action of muscles in making passive motion—for instance, at the wrist after Colles's fracture. If the fingers be extended, the wrist can be flexed to a right angle. If, however, they be first flexed as in "making a fist," flexion at the wrist is quickly limited to from forty to fifty degrees in different persons, and is very painful beyond that point. Hence passive motion here should be made with the fingers extended. In the leg, when flexing the hip, the knee should be flexed.'

ARTICULATION OF THE MANDIBLE

The parts entering into the formation of this joint are : above, the articular tubercle, and the anterior portion of the mandibular fossa of the temporal bone; below, the condyle of the mandible. The ligaments of the joint are the following :

The articular capsule.	Sphenomandibular.
Temporomandibular.	The articular disc.
	Stylomandibular.

FIG. 455.—Articulation of the mandible. Lateral aspect.

The articular capsule is a thin, loose envelope, attached, above, to the circumference of the mandibular fossa and the articular tubercle; below, to the neck of the condyle of the mandible. The synovial stratum of the articular capsule is continued over the upper and lower surfaces of the articular disc.

The temporomandibular ligament (external lateral ligament) (fig. 455) consists of two short, narrow fasciculi, one in front of the other, attached, above,

FIG. 455.—Articulation of the mandible.
Medial aspect.

to the lateral surface of the zygomatic process of the temporal bone and to the tubercle on its lower border; below, to the lateral surface and posterior border of the neck of the mandible. It is broader above than below, and its fibres are directed obliquely downwards and backwards.

The sphenomandibular ligament (fig. 456) is a flat, thin band which is attached above to the spina angularis of the sphenoidal bone, and, becoming broader as it descends, is fixed to the lingula of the mandibular foramen.* Its lateral surface is in relation, above, with the Pterygoideus externus; lower down, it is separated from the neck of the condyle by the internal maxillary vessels; still lower, the inferior alveolar vessels and nerve and a lobule of the

parotid gland lie between it and the ramus of the mandible. Its medial surface is in relation with the Pterygoideus internus.

The articular disc (fig. 457) is a thin, oval plate, placed between the condyle of the mandible and the mandibular fossa; it divides the joint into two cavities. Its upper surface is concavoconvex from before backwards, to accommodate itself to the form of the mandibular fossa and the articular tubercle. Its under surface, in contact with the condyle, is concave. Its circumference is connected to the articular capsule, and in front to the tendon of the Pterygoideus externus. It is thicker at its periphery, especially behind, than at its centre, where it is sometimes perforated. The fibres of which it is composed have a concentric arrangement, more apparent at the circumference than at the centre.

The stylomandibular ligament (fig. 456) is a specialised band of the fascia colli, which stretches from the apical part of the styloid process of the temporal bone to the angle and posterior border of the ramus of the mandible between the Masseter and Pterygoideus internus. It separates the parotid from the submaxillary gland, and from its deep surface some fibres of the Styloglossus take origin.

FIG. 457.—Sagittal section of the articulation of the mandible.

* J. Cameron (*Journal of Anatomy and Physiology*, vol. xlix.) points out that the cranial end of this ligament 'enters the inner extremity of the Glaserian fissure and whilst doing so is merely attached to the spine of the sphenoid by its inner edge.' He suggests that the attachment to the spina angularis of the sphenoidal bone is purely adventitious, and that the true morphological attachment is in reality to the lips of the fissure and also within the tympanic cavity, where a considerable proportion of the fibres are directly continuous with the fibrous layer of the membrane tympani. This intratympanic portion is usually described as the anterior ligament of the malleus. It forms a prominent band in a seven months fetus, and at this stage appears to be independent of the sphenoidal bone.

Although classed among the ligaments of the temporomandibular joint, it can only be considered as accessory to it.

The *nerves* of the temporomandibular joint are derived from the auriculo-temporal and masseteric branches of the mandibular nerve, the *arteries* from the superficial temporal branch of the external carotid artery, and from the internal maxillary artery.

Movements.—The movements permitted in this articulation are extensive. Thus, the mandible may be depressed or elevated, or carried forwards or backwards; a slight amount of side-to-side movement is also permitted. When the mouth is opened the body of the mandible is depressed, and the condyles and articular discs are pulled forwards on to the articular tubercles; in shutting the mouth the reverse action takes place. When the mandible is carried horizontally forwards, as in protruding the lower incisor teeth in front of the upper, the disc and the condyle glide forwards on the mandibular fossa and articular tubercle. The grinding or chewing movement is produced by one condyle, with its disc, gliding alternately forwards and backwards, while the other condyle moves simultaneously in the opposite directions; at the same time the condyle undergoes a vertical rotation on the disc. One condyle advances and rotates, while the other recedes and rotates.

The mandible is *depressed* by its own weight, assisted by the *Platysma*, and, when the hyoid bone is fixed by the *Digastricus*, the *Mylohyoideus*, and the *Geniohyoideus*; at the same time the condyles and the articular discs are drawn forwards by the *Pterygoidei externi*. It is *elevated* by the *Masseter*, *Pterygoideus internus*, and *Temporalis*. It is drawn *forwards* by the simultaneous action of the *Pterygoidei internus* and *externus*, the superficial fibres of the *Masseter* and the anterior fibres of the *Temporalis*; and *backwards* by the deep fibres of the *Masseter* and the posterior fibres of the *Temporalis*. The grinding movement is caused by the alternate action of the *Pterygoidei* of either side.

Applied Anatomy.—The mandible can be dislocated only in one direction—viz. forwards. The accident is caused by violence or by muscular action. When the mouth is open, the condyle is situated on the articular tubercle, and any sudden violence, or even a sudden muscular spasm, as during a convulsive yawn, may displace the condyle forwards into the infratemporal fossa. The displacement may be unilateral or bilateral. Reduction is accomplished by depressing the jaw with the thumbs placed on the last molar teeth, and at the same time elevating the chin. The downward pressure overcomes the spasm of the *Masseter*, *Temporalis*, and *Pterygoideus internus*, and elevation of the chin throws the condyle backwards; the above-mentioned muscles then draw the condyle back into its normal position.

In close relation to the condyle of the mandible are the external acoustic meatus and the tympanic cavity; any force, therefore, applied to the bone is liable to be attended with damage to these parts, or inflammation in the joint may extend to them. On the other hand inflammation of the tympanic cavity may involve the articulation and cause its destruction, thus leading to ankylosis of the joint. The joint is also occasionally the seat of osteo-arthritis, causing great suffering during efforts of mastication. A peculiar affection sometimes attacks the neck and condyle of the mandible, consisting in hypertrophy and elongation of these parts and consequent protrusion of the chin to the opposite side.

ARTICULATIONS OF THE VERTEBRAL COLUMN

The vertebræ from the third cervical to the first sacral inclusive are articulated to one another by: (1) a series of amphiarthrodial joints between the vertebral bodies; and (2) a series of diarthrodial joints between the vertebral arches.

1. ARTICULATIONS OF VERTEBRAL BODIES

The articulations between the bodies of the vertebræ are amphiarthrodial joints, and the individual vertebræ move only slightly on each other. When, however, this slight degree of movement between the pairs of bones takes

place in a considerable length of the vertebral column, the total range of movement is great. The ligaments of these articulations are the following :

Anterior longitudinal.

Posterior longitudinal.

Intervertebral fibrocartilages.

The **anterior longitudinal ligament** (fig. 466) is a broad and strong band of fibres, which extends along the anterior surfaces of the bodies of the vertebræ. It is broader below than above, thicker and narrower in the thoracic than in the cervical and lumbar regions, and somewhat thicker and narrower opposite the bodies of the vertebræ than opposite the intervertebral fibrocartilages. It is attached above, to the pharyngeal tubercle of the occipital bone, whence it extends to the anterior tubercle of the atlas, then to the front of the body of the epistropheus, and is continued down as far as the upper part of the front of the sacrum. It consists of dense longitudinal fibres, which are intimately adherent to the intervertebral fibrocartilages and the prominent

FIG. 458.—Median sagittal section of two lumbar vertebræ and their ligaments.

margins of the vertebræ, but not to the middle parts of the vertebral bodies. In the latter situation the ligament is thick and fills up the concavities on the anterior surfaces, and makes the front of the vertebral column more even. It is composed of several layers of fibres, of which the most superficial are the longest and extend between four or five vertebræ. The intermediate fibres extend between two or three vertebræ, while the deepest reach from one vertebra to the next. At the sides of the bodies the ligament consists of a few short fibres which pass from one vertebra to the next, separated from the concavities of the vertebral bodies by apertures for the passage of vessels.

The **posterior longitudinal ligament** (figs. 458, 459) is situated within the vertebral canal on the posterior surfaces of the bodies of the vertebræ. Above, it is attached to the basilar part of the occipital bone, and extends down, in intimate connexion with the membrana tectoria, to the body of the epistropheus, and is thence continued downwards to the sacrum. It is broader above than below, and thicker in the thoracic than in the cervical and lumbar regions. In the situation of the intervertebral fibrocartilages and contiguous margins of the vertebræ, where the ligament is more intimately adherent, it is broad, and in the thoracic and lumbar regions presents a series of dentations with intervening concave margins; but it is narrow and thick over the centres of the bodies, from which it is separated by the basivertebral veins.

This ligament is composed of smooth, shining fibres, denser and more compact than those of the anterior ligament, and consists of superficial layers occupying the interval between three or four vertebræ, and deeper layers which extend between adjacent vertebræ.

The intervertebral fibrocartilages (figs. 458, 459) are interposed between the adjacent surfaces of the bodies of the vertebræ, from the epistropheus to the sacrum, and form the chief bonds of connexion between the vertebræ.

FIG. 459.—Posterior longitudinal ligament of vertebræ, in lumbar region.

Their shape corresponds with that of the bodies between which they are placed. Their thickness varies in different regions of the column, and in different parts of the same fibrocartilage; they are thicker in front than behind in the cervical and lumbar regions, and thus contribute to the anterior convexities of these parts of the column; while they are of nearly uniform thickness in the thoracic region, the anterior concavity of this part of the column being almost entirely due to the shape of the vertebral bodies. They are adherent, by their surfaces, to thin layers of hyaline cartilage which cover the upper and under surfaces of the bodies of the vertebræ; in the lower cervical vertebræ, however, small joints with articular capsules are occasionally present between the upper surfaces of the bodies and the margins of the fibrocartilages on either side.

The intervertebral fibrocartilages are closely connected to the anterior and posterior longitudinal ligaments; in the thoracic region they are joined laterally, by means of the interarticular ligaments, to the heads of those ribs which articulate with two vertebræ. The intervertebral fibrocartilages constitute about one-fourth of the length of the vertebral column, exclusive of the first two vertebræ; but this amount is not equally distributed between the various bones, the cervical and lumbar portions having, in proportion to their length, a much greater amount than the thoracic region, with the result that these parts possess greater pliancy and freedom of movement.

Structure of the intervertebral fibrocartilages.—Each is composed, at its circumference, of laminae of fibrous tissue and fibrocartilage, forming the *annulus fibrosus*; and, at its centre, of a soft, pulpy, highly elastic substance, of a yellowish colour, which projects considerably above the surrounding level when the disc is divided horizontally. This pulpy substance (*nucleus pulposus*), especially well developed in the lumbar region, contains the remains of the notochord. The laminae are arranged concentrically; the outermost consist of ordinary fibrous tissue, the others of white fibrocartilage. The laminae are not quite vertical in their direction, those near the circumference being curved outwards and closely approximated; while those nearest the centre curve in the opposite direction, and are somewhat more widely separated. The fibres of which each lamina is composed are directed, for the most part, obliquely from above downwards, the fibres of adjacent laminae passing in opposite directions and varying in every layer: so that the fibres of one layer are directed across those of another, like the limbs of the letter X. This laminar arrangement exists in about the outer half of each fibrocartilage. The pulpy substance presents no such arrangement, and consists of a fine fibrous matrix, containing angular cells united to form a reticular structure.

Applied Anatomy.—When an aneurysm presses on the vertebral column, the vertebral bodies are often deeply eroded by it, while the intervertebral fibrocartilages remain intact. The fibrocartilages are the first to be destroyed, however, in tuberculosis of the vertebral column, where, as not infrequently happens, the disease begins in the fibrocartilages, and spreads thence to the bodies of the two adjoining vertebrae.

2. ARTICULATIONS OF VERTEBRAL ARCHES

The joints between the articular processes of the vertebrae belong to the arthrodial variety and are enveloped by articular capsules; while the laminae, spinous and transverse processes are connected by the following ligaments:

Ligamenta flava.
Supraspinal.

Ligamentum nuchae.
Interspinal.

Intertransverse.

The articular capsules (fig. 458) are thin and loose, and are attached to the margins of the articular processes of adjacent vertebrae; they are longer and looser in the cervical than in the thoracic and lumbar regions.

The ligamenta flava (fig. 460) connect the laminae of adjacent vertebrae, and are best seen from the interior of the vertebral canal. Their attachment

FIG. 460.—Ligamenta flava. A. from behind. B. in section.

extends from the articular capsules to the point where the laminae fuse to form the spinous process; here their posterior margins come into contact and are to a certain extent united, small intervals being left for the passage of vessels. The ligamenta flava consist of yellow elastic tissue, the fibres of which, almost perpendicular in direction, are attached to the anterior surface of the lamina above, some distance from its inferior margin, and to the posterior surface and upper margin of the lamina below. The ligaments are thin, but broad and long in the cervical region; they are thicker in the thoracic region,

and thickest in the lumbar region. Their marked elasticity serves to preserve the upright posture, and to assist the vertebral column in resuming it after flexion.

The **supraspinal ligament** (fig. 458) is a strong fibrous cord, which connects together the apices of the spinous processes from the seventh cervical vertebra to the sacrum; fibrocartilage is developed in the ligament at its points of attachment to the tips of the spinous processes. It is thicker and broader in the lumbar than in the thoracic region, and intimately blended in both situations with the neighbouring fascia. The most superficial fibres of this ligament extend over three or four vertebræ; those more deeply seated pass between two or three vertebræ; while the deepest connect the spinous processes of neighbouring vertebræ. Between the spinous processes it is continuous with the interspinal ligaments. (Between the spinous process of the seventh cervical vertebra and the external occipital protuberance its place is taken by the *ligamentum nuchæ*.)

The **ligamentum nuchæ** is a fibrous membrane, which, in the neck, represents the supraspinal ligament of the thoracic and lumbar vertebræ. It extends from the external protuberance and median nuchal line of the occipital bone to the spinous process of the seventh cervical vertebra. From its anterior border a fibrous lamina is given off, which is attached to the posterior tubercle of the atlas, and to the spinous processes of the cervical vertebræ, and forms a septum between the muscles on either side of the neck. In man it is the representative of an important elastic ligament, which, in some of the lower animals, serves to sustain the weight of the head.

The **interspinal ligaments** (fig. 458). thin and membranous, connect adjoining spinous processes, and their attachments extend from the root to the apex of each process. They meet the ligamenta flava in front and the supraspinal ligament behind. They are narrow and elongated in the thoracic region; broader, thicker, and quadrilateral in form in the lumbar region; and only slightly developed in the neck.

The **intertransverse ligaments** are interposed between the transverse processes. In the cervical region they consist of a few irregular, scattered fibres; in the thoracic region they are rounded cords intimately connected with the deep muscles of the back; in the lumbar region they are thin and membranous.

3. SACROCOCCYGEAL SYMPHYSIS

This articulation is an amphiarthrodial joint, between the apex of the sacrum and the base of the coccyx. It is homologous with the joints between the bodies of the vertebræ, and is connected by the following ligaments:

Anterior sacrococcygeal.	Lateral sacrococcygeal.
Posterior sacrococcygeal.	Fibrocartilaginous disc.

The **anterior sacrococcygeal ligament** consists of a few irregular fibres, which descend from the anterior surface of the sacrum to the front of the coccyx, blending with the periosteum.

The **posterior sacrococcygeal ligament** is a flat band, which arises from the margin of the lower orifice of the sacral canal, and descends to be inserted into the posterior surface of the coccyx. This ligament completes the lower and back part of the sacral canal, and is divisible into a short *deep* and a longer *superficial* part.

A **lateral sacrococcygeal ligament** exists on either side and connects the transverse process of the coccyx to the lower lateral angle of the sacrum; it completes the foramen for the fifth sacral nerve.

A thin disc of **fibrocartilage** is interposed between the contiguous surfaces of the sacrum and coccyx; it is somewhat thicker in front and behind than at the sides. Occasionally the coccyx is freely movable on the sacrum; in such cases an articular capsule lined by a synovial stratum is present.

The different segments of the coccyx are connected together by the extension downwards of the anterior and posterior sacrococcygeal ligaments, thin annular discs of fibrocartilage being interposed between the segments. In the adult

male, all the pieces become ossified together at a comparatively early period ; but in the female, this does not commonly occur until a later period of life. At a more advanced age the joint between the sacrum and coccyx is obliterated. Backward and forward movements take place between the sacrum and coccyx ; their extent increases during pregnancy.

Movements.—The movements permitted in the vertebral column are : flexion, extension, lateral movement, circumduction, and rotation.

In *flexion*, or movement forwards, the anterior longitudinal ligament is relaxed and the anterior parts of the intervertebral fibrocartilages are compressed ; while the posterior longitudinal ligament, the ligamenta flava, and the inter- and supraspinal ligaments are stretched, as well as the posterior fibres of the intervertebral fibrocartilages. The interspaces between the laminae are widened, and the inferior articular processes glide upwards upon the superior articular processes of the subjacent vertebrae. Flexion is the most extensive of all the movements of the vertebral column, and is freest in the lumbar region.

In *extension*, or movement backwards, an exactly opposite disposition of the parts takes place. This movement is limited by the anterior longitudinal ligament, and by the approximation of the spinous processes. It is freest in the cervical region.

In *lateral movements*, the sides of the intervertebral fibrocartilages are compressed, the extent of motion being limited by the resistance offered by the surrounding ligaments. Lateral movements may take place in any part of the column, but are freest in the cervical and lumbar regions.

Circumduction is very limited, and is merely a succession of the preceding movements.

Rotation is produced by the twisting of the intervertebral fibrocartilages ; this, although only slight between any two vertebrae, allows of a considerable extent of movement when it takes place in the whole length of the column, the front of the upper part of the column being turned to one or other side. This movement occurs to a slight extent in the cervical region, is freer in the upper part of the thoracic region, and absent in the lumbar region.

The extent and variety of the movements are influenced by the shape and direction of the articular surfaces. In the *cervical* region the upward inclination of the superior articular surfaces allows of free flexion and extension. Extension can be carried farther than flexion ; at the upper end of the region it is checked by the locking of the posterior edges of the superior atlantal facets in the condyloid fossae of the occipital bone ; at the lower end it is limited by a mechanism whereby the inferior articular processes of the seventh cervical vertebra slip into grooves behind and below the superior articular processes of the first thoracic. Flexion is arrested just beyond the point where the cervical convexity is straightened ; the movement is checked by the apposition of the projecting lower lips of the bodies of the vertebrae with the shelving surfaces on the bodies of the subjacent vertebrae. Lateral flexion and rotation are free in the cervical region, and are always combined : the upward and medial inclinations of the superior articular surfaces impart a rotatory movement during lateral flexion.

In the *thoracic* region, notably in its upper part, all the movements are limited in order to reduce interference with respiration to a minimum. The almost complete absence of an upward inclination of the superior articular surfaces prohibits any marked flexion, while extension is checked by the contact of the inferior articular margins with the laminae, and the contact of the spinous processes with one another. Rotation is free in the thoracic region : the superior articular processes are segments of a cylinder whose axis is in the mid-ventral line of the vertebral bodies. The direction of the articular facets would allow of free lateral flexion, but this movement is considerably limited in the upper part of the region by the resistance of the ribs and sternum.

In the *lumbar* region flexion and extension are free. The inferior articular facets are not in close apposition with the superior facets of the subjacent vertebrae, and on this account a considerable amount of lateral flexion is permitted. For the same reason a slight amount of rotation can be carried out, but this is so soon checked by the interlocking of the articular surfaces that it is negligible.

The principal muscles which produce *flexion* are the Sternocleidomastoides, Longus capitis and Longus colli, the Scalenii, the abdominal muscles, and the Psoas major. *Extension* is produced by the intrinsic muscles of the back, assisted in the

neck by the Splenius, Semispinales dorsi and cervicis, and the Multifidus. *Lateral* motion is produced by the intrinsic muscles of the back, by the Splenius, the Scaleni, the Quadratus lumborum, and the Psoas major, the muscles of one side only acting ; and *rotation* by the action of the following muscles of one side only, viz. the Sternocleidomastoideus, the Longus capitis, the Scaleni, the Multifidus, the Semispinalis capitis, and the abdominal muscles.

4. ARTICULATION OF THE ATLAS WITH THE EPISTROPHEUS

The articulation of the atlas with the epistropheus is of a complicated nature and comprises three joints. There is a pivot articulation between the dens of the epistropheus and the ring formed by the anterior arch and

FIG. 461.—Anterior atlanto-occipital membrane.

the transverse ligament of the atlas (see fig. 463), and a pair of arthrodial or gliding joints between the articular processes of the two bones. The ligaments connecting these bones are :

Two articular capsules.

Transverse.

The articular capsules are thin and loose, and surround the joints between the articular surfaces of the bones. Each is strengthened at its posterior and medial part by an *accessory ligament*, which is attached below to the body of the epistropheus near the base of the dens, and above to the lateral mass of the atlas near the transverse ligament.

In front, the two vertebræ are connected by a continuation of the anterior longitudinal ligament (fig. 461). In this position it is a strong membrane, fixed, above, to the lower border of the anterior arch of the atlas, and below, to the front of the body of the epistropheus. It is strengthened in the middle line by a rounded cord, which connects the tubercle on the anterior arch of the atlas to the body of the epistropheus.

Behind, the atlas and epistropheus are joined by a broad, thin membrane (fig. 462) attached, above, to the lower border of the posterior arch of the atlas, below, to the upper edges of the laminæ of the epistropheus ; it is in series with the ligamenta flava.

The transverse ligament of the atlas (figs. 463, 464, 465) is a thick, strong band, which arches across the ring of the atlas, and retains the dens of the epistropheus in contact with the anterior arch. It is concave in front,

FIG. 462.—Posterior atlanto-occipital membrane.

convex behind, broader in the middle than at the ends, and firmly attached on either side to a small tubercle on the medial surface of the lateral mass of the atlas. As it crosses the dens, a small fasciculus (*crus superius*) is prolonged upwards, and another (*crus inferius*) downwards, from the superficial or posterior fibres of the ligament. The former is attached to the basilar part of the occipital bone in close relation with the membrana tectoria; the latter

FIG. 463.—Articulation between the dens and the atlas.

is fixed to the posterior surface of the body of the epistropheus; hence the whole ligament is named the *ligamentum cruciatum atlantis*. The transverse ligament divides the ring of the atlas into two unequal parts: of these, the posterior and larger serves for the transmission of the medulla spinalis and its membranes and the spinal parts of the accessory nerves; the anterior and

FIG. 464.—Membrana tectoria, transverse, and alar ligaments. The crus superius of the transverse ligament is drawn to one side.

FIG. 465.—Median sagittal section through the occipital bone and first three cervical vertebrae.

smaller contains the dens. The neck of the dens is constricted where it is embraced posteriorly by the transverse ligament, so that this ligament suffices to retain the process in position after all the others have been divided.

The joint-cavity between the dens and the transverse ligament is often continuous with those of the atlanto-occipital articulations.

Movements.—This articulation with its three joints allows the rotation of the atlas (and, with it, the skull) upon the epistropheus, the extent of rotation being limited by the alar ligaments.

The opposed surfaces of the articular processes of the atlas and epistropheus are not reciprocally curved; both are convex in their long axes. When, therefore, the upper facet glides forwards on the lower it also descends; the fibres of the articular capsule are relaxed in a vertical direction, and will then permit of movement in an anteroposterior direction. By this means a shorter capsule suffices and the strength of the joint is materially increased.

The principal muscles by which these movements are produced are the Sternocleidomastoideus and Semispinalis capitis of one side, acting with the Longus capitis, Splenius, Longissimus capitis, Rectus capitis posterior major, and Obliquus capitis inferior of the other side.

ARTICULATIONS OF THE VERTEBRAL COLUMN WITH THE CRANIUM

The ligaments connecting the vertebral column with the cranium may be divided into two sets; those uniting the atlas with the occipital bone, and those connecting the epistropheus with the occipital bone

1. ARTICULATION OF THE ATLAS WITH THE OCCIPITAL BONE

The articulation between the atlas and the occipital bone consists of a pair of condyloid joints. The ligaments connecting the bones are:

Two articular capsules.	Posterior atlanto-occipital
Anterior atlanto-occipital membrane.	membrane.

The articular capsules surround the condyles of the occipital bone, and connect them with the articular processes of the atlas: they are thin and loose. Their lateral portions are directed obliquely upwards and medialwards, and are reinforced by bundles of fibres, which are attached above to the jugular processes of the occipital bone, and below to the bases of the transverse processes of the atlas.

The atlanto-occipital joints frequently communicate with the joint between the dens and the transverse ligament of the atlas.

The anterior atlanto-occipital membrane (fig. 461) is broad, and composed of densely woven fibres which pass between the anterior margin of the foramen magnum above, and the upper border of the anterior arch of the atlas below; laterally, it is continuous with the articular capsules; in front, it is strengthened in the middle line by the continuation of the anterior longitudinal ligament, a strong, rounded cord, which connects the basilar part of the occipital bone to the tubercle on the anterior arch of the atlas.

The posterior atlanto-occipital membrane (fig. 462), broad but thin, is connected, above, to the posterior margin of the foramen magnum; below, to the upper border of the posterior arch of the atlas. On either side it is defective below, over the groove for the vertebral artery, and forms with this groove an opening for the entrance of the artery and the exit of the first cervical nerve. The free border of the membrane, arching over the artery and nerve, is sometimes ossified.

Movements.—The movements permitted in this joint are (a) flexion and extension, which give rise to the ordinary forward and backward nodding of the head, and (b) slight lateral motion to one or other side. *Flexion* is produced mainly by the action of the Longi capitis and Recti capitis anteriores; *extension* by the Recti capitis posteriores major and minor, the Obliquus superior, the Semispinalis capitis, Splenius capitis, Sternocleidomastoideus, and upper fibres of the Trapezius. The Recti laterales are concerned in the lateral movement, assisted by the Trapezius,

Splenius capitis, Semispinalis capitis, and the Sternocleidomastoides of the same side, all acting together.

2. LIGAMENTS CONNECTING THE EPISTROPHÆUS WITH THE OCCIPITAL BONE

Membrana tectoria.

Two alar.

Ligamentum apicis dentis.

The *membrana tectoria* (occipito-axial ligament) (figs. 464, 465) is situated within the vertebral canal. It is a broad, strong band, which covers the dens and its ligaments, and appears to be a prolongation upwards of the posterior longitudinal ligament of the vertebral column. It is fixed, below, to the posterior surface of the body of the epistropheus, and, expanding as it ascends, is attached above to the basilar part of the occipital bone, in front of the foramen magnum, where it blends with the cranial dura mater.

The *alar ligaments* (fig. 464) are two strong, rounded cords, which arise one on either side of the upper part of the dens, and, passing obliquely upwards and lateralwards, are inserted into rough impressions on the medial sides of the condyles of the occipital bone. The alar ligaments limit rotation of the cranium and therefore receive the name of *check ligaments*. Between them is the *ligamentum apicis dentis* (fig. 465), which extends from the tip of the dens to the anterior margin of the foramen magnum, being intimately blended with the deep portion of the anterior atlanto-occipital membrane and with the superior crus of the transverse ligament of the atlas. It is regarded as a rudimentary intervertebral fibrocartilage, and traces of the notochord may persist in it.

In addition to the ligaments which unite the atlas and epistropheus to the skull, it must be remembered that the *ligamentum nuchæ* (p. 352) connects the cervical vertebræ with the cranium.

Applied Anatomy.—The ligaments of the vertebral column are so strong, and the bones so interlocked by the arrangement of their articulating processes, that dislocation is very uncommon, and, even in the upper part of the neck, rarely occurs unless accompanied by fracture. Dislocation of the occipital bone from the atlas has been recorded only in one or two cases, but dislocation of the atlas from the epistropheus, with rupture of the transverse ligament of the atlas, is much more common: it is the mode in which death is produced in many cases of execution by hanging. Below the third cervical vertebra, dislocation without fracture occasionally takes place.

COSTOVERTEBRAL ARTICULATIONS

The articulations of the ribs with the vertebral column may be divided into two sets, one connecting the heads of the ribs with the bodies of the vertebræ, another uniting the necks and tubercles of the ribs with the transverse processes.

1. ARTICULATIONS OF THE HEADS OF THE RIBS (fig. 466)

These consist of a series of arthrodia, and are sometimes named *costocentral joints*. They are formed by the articulation of the heads of the typical ribs with the foveæ on the contiguous margins of the bodies of the thoracic vertebræ and with the intervertebral fibrocartilages between them; the first, tenth, eleventh, and twelfth ribs each articulate with a single vertebra. The ligaments of the joints are:

The articular capsules.

Radiate.

Interarticular.

In the majority of these articulations, viz. the second to the ninth inclusive, two articular capsules are present, since the joint is divided into two by an interarticular ligament. The articular capsules connect the heads of the ribs with the circumferences of the articular cavities formed by the intervertebral fibrocartilages and the adjacent vertebræ. Some of their upper fibres pass through the intervertebral foramen to the back of the intervertebral fibrocartilage, while the posterior fibres are continuous with the ligament of the neck of the rib.

The radiate ligament (stellate ligament) connects the anterior part of the head of each rib with the sides of the bodies of two vertebræ, and the intervertebral fibrocartilage between them. It is attached to the anterior part of the head of the rib, just beyond the articular surface. The superior fibres ascend and are connected with the body of the vertebra above; the inferior fibres descend to the body of the vertebra below; the middle fibres, the smallest and least distinct, are horizontal and attached to the intervertebral fibrocartilage.

In the case of the first rib, this ligament is attached to the body of the last cervical vertebra, as well as to that of the first thoracic. In the articulations of the heads of the tenth, eleventh, and twelfth ribs, each of which articulates with a single vertebra, the fibres of the ligament in each case are connected to the vertebra above, as well as to that with which the rib articulates.

FIG. 466.—Costovertebral articulations. Anterior view.

The interarticular ligament is situated in the interior of the joint. It consists of a short band of fibres, flattened from above downwards, attached laterally to the crest separating the two articular facets on the head of the rib, and medially to the intervertebral fibrocartilage; it divides the joint into two cavities and is covered on its upper and lower surfaces by the synovial strata of the articular capsules. In the joints of the first, tenth, eleventh, and twelfth ribs, the interarticular ligament does not exist; consequently, there is but one cavity in each of these articulations. This ligament is the homologue of the *ligamentum conjugale* present in some mammals, and uniting the heads of opposite ribs across the back of the intervertebral fibrocartilage.

2. COSTOTRANSVERSE ARTICULATIONS (fig. 467)

The articular portion of the tubercle of the rib forms with the articular surface on the adjacent transverse process an arthrodiar joint. In the eleventh and twelfth ribs this articulation is wanting.

The ligaments of the joint are :

The articular capsule.
Anterior costotransverse.
Ligament of the tubercle of the rib.

Posterior costotransverse.
Ligament of the neck of the rib.
Ligament of the tubercle of the rib.

The ~~articular~~ capsule is a thin membrane attached to the circumference of the articular surfaces, and lined by a synovial stratum.

The anterior costotransverse ligament is attached below to the crest on the upper border of the neck of the rib, and passes obliquely upwards and lateralwards to the lower border of the transverse process immediately above. It is in relation, in front, with the intercostal vessels and nerve; its medial border is thickened and free, and forms the lateral boundary of an aperture

FIG. 467.—Costotransverse articulations. Seen from above.

which transmits the posterior branches of the intercostal vessels and the posterior division of the intercostal nerve; its lateral border is continuous with a thin aponeurosis which covers the *Intercostalis externus*.)

The first rib has no anterior costotransverse ligament. The neck of the twelfth rib is connected to the base of the transverse process of the first lumbar vertebra by a band of fibres, named the *lumbocostal ligament*; it is in series with the anterior costotransverse ligaments.

The posterior costotransverse ligament is a feeble band which is attached below to the neck of the rib, behind and medial to the anterior costotransverse ligament; it passes upwards and medialwards to the base of the transverse process and lateral border of the inferior articular process of the vertebra above.

The ligament of the neck of the rib (*interosseous costotransverse ligament*) consists of short but strong fibres, connecting the rough surface on the back of the neck of the rib with the anterior surface of the adjacent transverse process. A rudimentary ligament may be present in the case of the eleventh and twelfth ribs.

The ligament of the tubercle of the rib is a short but thick and strong fasciculus, which passes obliquely from the apex of the transverse process to the rough non-articular portion of the tubercle of the rib. The ligaments attached to the upper ribs ascend from the transverse processes; they are shorter and more oblique than those attached to the inferior ribs, which descend slightly.

Movements.—The heads of the ribs are so closely connected to the bodies of the vertebræ by the radiate and interarticular ligaments that only slight gliding movements of the articular surfaces on one another can take place. Similarly, the strong ligaments binding the necks and tubercles of the ribs to the transverse processes limit the movements of the costotransverse joints to slight gliding, the nature of which is determined by the shape and direction of the articular surfaces (fig. 468). On the upper six ribs the articular surfaces on the tubercles are oval in shape and convex from above downwards; they fit into corresponding concavities on the anterior surfaces of the transverse processes, so that upward and downward movements of the tubercles are associated with rotation of the rib-neck on its long axis. On the seventh, eighth, ninth, and tenth ribs the articular surfaces on the tubercles are flat, and are directed obliquely downwards, medialwards, and backwards. The surfaces with which they articulate are placed on the upper margins of the transverse processes; when, therefore, the tubercles are drawn up they are at the same time carried backwards and medialwards. The two joints, costocentral and costotransverse, move simultaneously and in the same directions, the total effect being that the neck of the rib moves as if on a single joint, of which the costocentral and costotransverse articulations form the ends. In the upper six ribs the neck of the rib moves but slightly upwards and downwards; its chief movement is one of rotation round its own long axis, rotation backwards being associated with depression, rotation forwards with elevation. In the seventh, eighth, ninth, and tenth ribs the neck of the rib moves upwards, backwards, and medialwards, or downwards, forwards, and lateralwards; very slight rotation accompanies these movements.

FIG. 468.—Section of the costotransverse joints from the third to the ninth inclusive. Contrast the concave facets on the upper with the flattened facets on the lower transverse processes.

STERNOCOSTAL ARTICULATIONS (fig. 469)

The cartilages of the true ribs, with the exception of the first, articulate with the sternum by arthrodial joints. The cartilage of the first rib is directly united with the sternum, and the joint between this rib and the sternum is a synchondrosis.

The ligaments of the arthrodial joints are :

The articular capsules.
Radiate sternocostal.

Interarticular sternocostal.
Costoxiphoid.

The **articular capsules** surround the joints between the sternum and the cartilages of the ribs from the second to the seventh inclusive. They are very thin, intimately blended with the radiate sternocostal ligaments, and strengthened at the upper and lower parts of the articulations by a few fibres, which connect the cartilages to the side of the sternum.

The **radiate sternocostal ligaments** are broad, thin membranous bands which radiate from the front and back of the sternal ends of the cartilages of the true ribs to the anterior and posterior surfaces of the sternum. Their superficial fibres intermingle with the fibres of the ligaments above and below them, with those of the opposite side, and on the front of the sternum with the tendinous fibres of origin of the Pectoralis major, forming a thick fibrous membrane (*membrana sterni*) which envelops the bone, and is more distinct at its lower than at its upper part.

The interarticular sternocostal ligaments are found constantly only between the second costal cartilages and the sternum. The cartilage of the *second rib* is connected with the sternum by means of an interarticular ligament, attached laterally to the cartilage of the rib, and medially to the fibrocartilage which unites the manubrium and body of the sternum. Occasionally the cartilage of the *third rib* is connected with the first and second pieces of the body

FIG. 469.—Sternocostal and interchondral articulations. Anterior view.

of the sternum by an interarticular ligament. Still more rarely, similar ligaments are found in the other four joints of the series. In the lower two an interarticular ligament sometimes obliterates the joint-cavity, so as to convert the articulation into an amphiarthrosis. After middle life the articular surfaces lose their polish, become roughened, and the synovial strata apparently disappear. In old age, the cartilages of most of the ribs become continuous with the sternum, and the joint-cavities are consequently obliterated.

The costoxiphoid ligaments connect the anterior and posterior surface of the seventh costal cartilage, and sometimes those of the sixth, to the front

and back of the xiphoid process. They vary in length and breadth in different subjects; those on the back of the joint are less distinct than those in front.

Movements.—Slight gliding movements are permitted in the sternocostal articulations.

INTERCHONDRAL ARTICULATIONS (fig. 469)

The contiguous borders of the sixth and seventh, the seventh and eighth, the eighth and ninth, and sometimes the ninth and tenth, costal cartilages articulate with each other by small smooth, oblong facets. Each articulation is enclosed in a thin *articular capsule*, lined by a synovial stratum and strengthened laterally and medially by *interchondral ligaments* which pass from one cartilage to the other. Sometimes the fifth costal cartilages, more rarely the ninth and tenth, articulate by their lower borders with the adjoining cartilages by small oval facets; more frequently the connexion is by a few ligamentous fibres.

COSTOCHONDRAL ARTICULATIONS

The lateral end of each costal cartilage is received into a depression in the sternal end of the rib, and the two are enveloped by the periosteum.

ARTICULATION OF THE MANUBRIUM WITH THE BODY OF THE STERNUM

In the majority of cases the joint between the manubrium and the body of the sternum is a symphysis, the bony surfaces being coated with cartilage and connected by a disc of fibrocartilage which tends to ossify in advanced life. In rather more than thirty per cent. of cases the central part of the disc undergoes absorption and the joint is converted into a diarthrodial one. The two segments of the bone are also connected by the *membrana sterni*.

MECHANISM OF THE THORAX

Each rib possesses its own range and variety of movements, but the movements of all are combined in the respiratory excursions of the thorax. Each rib may be regarded as a lever, the fulcrum of which is situated immediately outside the costotransverse articulation, so that when the body of the rib is elevated the neck is depressed and *vice versa*; from the disproportion in length of the arms of the lever a slight movement at the vertebral end of the rib is greatly magnified at the anterior extremity.

The anterior ends of the ribs lie on a lower plane than the posterior; when therefore the body of the rib is elevated the anterior extremity is also thrust forwards. Again, the middle of the body of the rib lies in a plane below that passing through the two extremities, so that when the body is elevated relatively to its ends it is at

FIG. 470.—Lateral view of first and seventh ribs in position, showing the movements of the sternum and ribs in, A, ordinary expiration; B, quiet inspiration; C, deep inspiration.

the same time carried outwards from the median plane of the thorax; further, each rib forms the segment of a curve which is greater than that of the rib immediately

above. Therefore the elevation of a rib increases the transverse diameter of the thorax in the plane to which it is raised. The modifications of the rib movements at their vertebral ends have already been described (p. 361). Further modifications result from the attachments of their anterior extremities, and it is convenient therefore to consider separately the movements of the ribs of the three groups—vertebrosternal, vertebrochondral, and vertebral.

Vertebrosteral ribs (figs. 470, 471).—The first rib differs from the others of this group in that its attachment to the sternum is a rigid one; this is counterbalanced to some extent by the fact that its head possesses no interarticular ligament, and is therefore more movable. The first pair of ribs with the manubrium sterni move as a single piece, the anterior portion being elevated by rotatory movements at the vertebral extremities. In normal quiet respiration the movement of this arc is practically *nil*; when it does occur the anterior part is raised and carried forwards, increasing the anteroposterior and transverse diameters of this region of the chest.

FIG. 471.—Diagram showing the axes of movement (AB and CD) of a vertebrosteral rib. The interrupted lines indicate the position of the rib in inspiration.

FIG. 472.—Diagram showing the axis of movement (AB) of a vertebrochondral rib. The interrupted lines indicate the position of the rib in inspiration.

The movement of the second rib is also slight in normal respiration, as its anterior extremity is fixed to the manubrium, and prevented therefore from moving upwards. The sternocostal articulation, however, allows the middle of the body of the rib to be drawn up, and in this way the transverse thoracic diameter is increased. Elevation of the third, fourth, fifth, and sixth ribs raises and thrusts forwards their anterior extremities, the greater part of the movement being effected by the rotation of the rib-neck backwards. The thrust of the anterior extremities carries forwards and upwards the body of the sternum, which moves on the joint between it and the manubrium, and thus the anteroposterior thoracic diameter is increased. This movement is, however, soon arrested, and the elevating force is then expended in raising the middle part of the body of the rib and everting its lower border; at the same time the costochondral angle is opened out. By these latter movements a considerable increase in the transverse diameter of the thorax is effected.

Vertebrochondral ribs (fig. 472).—The seventh rib is included with this group, as it conforms more closely to their type. While the movements of these ribs assist in enlarging the thorax for respiratory purposes, they are also concerned in increasing the upper abdominal space for viscera displaced by the action of the Diaphragm. The costal cartilages articulate with one another, so that each pushes up that above it, the final thrust being directed to pushing forwards and upwards the lower end

of the body of the sternum. The amount of elevation of the anterior extremities is limited on account of the very slight rotation of the rib-neck. Elevation of the shaft is accompanied by an outward and backward movement; the outward movement everts the anterior end of the rib and opens up the subcostal angle, while the backward movement pulls back the anterior extremity and counteracts the forward thrust due to its elevation; this latter is most noticeable in the lower ribs, which are the shortest. The total result is a considerable increase in the transverse and a diminution in the median anteroposterior diameter of the upper part of the abdomen; at the same time, however, the lateral anteroposterior diameters of the abdomen are increased.

Vertebral ribs.—Since these ribs have free anterior extremities and only costo-central articulations with no interarticular ligaments, they are capable of slight movements in all directions. When the other ribs are elevated these are depressed and fixed to form points of action for the Diaphragm.

ARTICULATIONS OF THE UPPER EXTREMITY

The articulations of the upper extremity comprise the following :

- | | |
|--------------------------|--------------------------|
| I. Sternoclavicular. | VI. Radiocarpal (wrist). |
| II. Acromioclavicular. | VII. Intercarpal. |
| III. Humeral (shoulder). | VIII. Carpometacarpal. |
| IV. Cubital (elbow). | IX. Intermetacarpal. |
| V. Radio-ulnar. | X. Metacarpophalangeal. |
| | XI. Digital. |

I. STERNOCLAVICULAR ARTICULATION (fig. 473)

The sternoclavicular articulation is a double arthrodial joint. The parts entering into its formation are the sternal end of the clavicle, the upper and lateral part of the manubrium sterni, and the cartilage of the first rib. The

FIG. 473.—Sternoclavicular articulation. Anterior view.

articular surface of the clavicle is much larger than that of the sternum, and is invested with a layer of cartilage,* which is considerably thicker than that on the latter bone. The ligaments of this joint are :

The articular capsule.
Sternoclavicular.

Interclavicular.
Costoclavicular.

The articular disc.

* According to Bruch, the sternal end of the clavicle is covered by a tissue which is fibrous rather than cartilaginous in structure.

The articular capsule surrounds the articulation; in front and behind it is of considerable thickness, but above, and especially below, it is thin and partakes more of the character of areolar than of true fibrous tissue.

The sternoclavicular ligament is a broad band, covering the anterior surface of the articulation; it is attached above to the upper and front part of the sternal end of the clavicle, and, passing obliquely downwards and medially, is attached below to the front of the upper part of the manubrium sterni.

The interclavicular ligament is a curved band, which varies considerably in size in different individuals; it is continuous above with the fascia colli (deep cervical fascia); it passes from the upper part of the sternal end of one clavicle to that of the other, and is also attached to the upper margin of the sternum.

The costoclavicular ligament (rhomboid ligament) is short, flat, strong, and rhomboid in form. Attached below to the upper surface of the cartilage of the first rib, it ascends backwards and lateralwards, and is fixed above to the costal tuberosity on the under surface of the clavicle.

The articular disc is flat and nearly circular, and is interposed between the articulating surfaces of the sternum and clavicle. It is attached, above to the upper and posterior border of the articular surface of the clavicle; below to the cartilage of the first rib, near its junction with the sternum; and by its circumference to the articular capsule. It is thicker at the circumference than at the centre, and divides the joint into two cavities; each of its surfaces is clothed by a synovial stratum.

The arteries supplying the joint are derived from the internal mammary and suprascapular arteries; the nerves, from the anterior supraclavicular nerves.

Movements.—This articulation admits of a limited amount of motion in nearly every direction—upwards, downwards, backwards, forwards, as well as circumduction.) When these movements take place in the joint, the clavicle in its motion carries the scapula with it, this bone gliding on the outer surface of the chest. (This joint therefore forms the centre from which all movements of the supporting arch of the shoulder originate, and is the only point of articulation of the shoulder girdle with the trunk.) (The movements attendant on elevation and depression of the shoulder take place between the clavicle and the articular disc.) When the shoulder is moved forwards and backwards, the clavicle, with the articular disc, rolls to and fro on the articular surface of the sternum. Elevation of the shoulder is limited principally by the costoclavicular ligament; depression, by the interclavicular ligament and articular disc. The muscles which *raise* the shoulder are the upper fibres of the Trapezius, the Levator scapulæ, and the clavicular head of the Sternocleidomastoideus, assisted to a certain extent by the Rhomboidei which pull the vertebral border of the scapula backwards and upwards and so raise the shoulder. *Depression* of the shoulder is principally effected by gravity, assisted by the Subclavius, Pectoralis minor, and lower fibres of the Trapezius. The shoulder is drawn *backwards* by the Rhomboidei and the middle and lower fibres of the Trapezius, and *forwards* by the Serratus anterior and Pectoralis minor.

Applied Anatomy.—The strength of this joint mainly depends upon its ligaments, and it is owing to these, and to the fact that the force of the blow is usually transmitted along the long axis of the clavicle, that dislocation rarely occurs, and that the bone is broken rather than displaced. When dislocation does occur, the course which the displaced bone takes depends more upon the direction in which the violence is applied than upon the anatomical construction of the joint; it may be either forwards, backwards or upwards. Should it be displaced backwards it may cause pressure on the trachea. The chief point worthy of note, as regards the construction of the joint, in connexion with dislocation, is the fact that, owing to the shape of the articular surfaces, and the strength of the joint mainly depending upon the ligaments, the displacement when reduced is very liable to recur, and hence it is extremely difficult to keep the end of the bone in its proper place.

ACROMIOCLAVICULAR ARTICULATION

The acromioclavicular articulation (fig. 474) is an arthrodial joint between the acromial end of the clavicle and the medial margin of the acromion of the scapula. Its ligaments are :

The articular capsule.
Acromioclavicular.
The articular disc.

Coracoclavicular { Trapezoid
and
Conoid.

The articular capsule completely surrounds the articular margins, and is strengthened above by the acromioclavicular ligament.

FIG. 474.—The left shoulder-joint and acromioclavicular joint and the ligaments of the scapula.

The acromioclavicular ligament is a quadrilateral band, covering the superior part of the articulation, and extending between the upper part of the acromial end of the clavicle and the adjoining part of the upper surface of the acromion ; it is composed of parallel fibres, which interlace with the aponeuroses of the Trapezius and Deltoides.

The articular disc is frequently absent from this articulation. When present, it generally only partially separates the articular surfaces and occupies the upper part of the articulation. More rarely, it completely divides the joint into two cavities.

The coracoclavicular ligament (fig. 474) connects the clavicle with the coracoid process of the scapula. It does not properly belong to the acromioclavicular articulation, but is usually described with it since it forms a most efficient means of retaining the clavicle in contact with the acromion. It consists of two parts, viz. the trapezoid and conoid ligaments, which are usually separated by a bursa.

The trapezoid ligament, the anterior and lateral fasciculus, is broad, thin, and quadrilateral. It is attached, below, to the upper surface of the coracoid

process; above, to the oblique ridge on the under surface of the clavicle. Its anterior border is free, its posterior is joined with the conoid ligament, the two forming, by their junction, an angle projecting backwards.

The *conoid ligament*, the posterior and medial fasciculus, is a dense band of fibres, conical in form, with its base directed upwards. It is attached by its apex to a rough impression at the base of the coracoid process, medial to the trapezoid ligament; above, by its base, to the coracoid tuberosity on the under surface of the clavicle, and to a line proceeding medialwards from it for 1.25 cm.

The *arteries* supplying the joint are derived from the transverse scapular and thoraco-acromial arteries; the *nerves*, from the *suprascapular* and *axillary* nerves.

Movements.—The movements of this articulation are of two kinds: (1) a *gliding* motion of the articular end of the clavicle on the acromion; (2) *rotation* of the scapula forwards and backwards upon the clavicle. The extent of this rotation is limited by the two portions of the coracoclavicular ligament, the trapezoid limiting rotation forwards, and the conoid backwards.

The acromioclavicular joint has important functions in the movements of the upper extremity. Humphry pointed out * that if there had been no joint between the clavicle and scapula, the circular movement of the scapula on the ribs (as in throwing the shoulders backwards or forwards) would have been attended with a greater alteration in the direction of the shoulder than is consistent with the free use of the arm in such positions, and it would have been impossible to give a blow straight forwards with the full force of the arm: that is to say, with the combined force of the scapula, arm, and forearm. 'This joint,' as he happily says, 'is so adjusted as to enable either bone to turn in a hinge-like manner upon a vertical axis drawn through the other, and it permits the surfaces of the scapula, like the baskets in a roundabout swing, to look the same way in every position, or nearly so.' Again, when the whole arch formed by the clavicle and scapula rises and falls (in elevation or depression of the shoulder), the joint between these two bones enables the scapula still to maintain its lower part in contact with the ribs.

Applied Anatomy.—The acromioclavicular joint owes its security mainly to the coracoclavicular ligament, which limits the amount of movement of the acromial end of the clavicle either upwards, backwards, or forwards. Owing to the slanting shape of the articular surfaces of this joint, dislocation generally occurs upwards; that is to say, the acromial end of the clavicle is displaced above the acromion of the scapula. The displacement is often incomplete, on account of the strong coracoclavicular ligaments, which remain unturned. The same difficulty exists, as in the sternoclavicular dislocation, in maintaining the end of the bone in position after reduction.

LIGAMENTS OF THE SCAPULA

The ligaments of the scapula (fig. 474) are:

Coraco-acromial.

Superior and Inferior transverse.

The *coraco-acromial ligament* is a strong triangular band, extending between the coracoid process and the acromion. Its apex is attached to the summit of the acromion just in front of the articular surface for the clavicle; and its base to the whole length of the lateral border of the coracoid process. This ligament, together with the coracoid process and the acromion, forms a vault for the protection of the head of the humerus. It sometimes consists of two strong marginal bands and a thinner intervening portion, the two bands being attached respectively to the apex and the base of the coracoid process, and joining together at the acromion.

When the Pectoralis minor is inserted, as occasionally is the case, into the capsule of the shoulder-joint instead of into the coracoid process, it passes between these two bands, and the intervening portion of the ligament is then deficient.

The *superior transverse ligament* (*suprascapular ligament*) converts the scapular notch into a foramen, and is sometimes ossified. It is a thin and flat fasciculus, narrower at the middle than at the extremities, which are attached

* *A Treatise on the Human Skeleton.*

to the base of the coracoid process and the medial end of the scapular notch respectively. The suprascapular nerve runs through the foramen; the transverse scapular vessels cross over the ligament.

The **inferior transverse ligament** (spinoglenoid ligament) is a weak membranous band, situated behind the neck of the scapula and stretching from the lateral border of the spine of the scapula to the margin of the glenoid cavity. It forms an arch under which the transverse scapular vessels and suprascapular nerve enter the infraspinatus fossa. It is frequently absent.

III. HUMERAL ARTICULATION OR SHOULDER-JOINT

The shoulder-joint (fig. 474) is an enarthrodial or ball-and-socket joint. The bones entering into its formation are the hemispherical head of the humerus and the shallow glenoid cavity of the scapula, an arrangement which permits of very considerable movement, while the joint itself is protected against displacement, by the muscles which surround it. The joint is also protected above by an arch, formed by the coracoid process, the acromion, and the coraco-acromial ligament. The articular cartilage on the head of the humerus is thicker at the centre than at the circumference, the reverse being the case with the articular cartilage of the glenoid cavity. The ligaments of the articulation are :

The articular capsule.
Coracohumeral.

The glenoidal labrum.
Transverse humeral.

The **articular capsule** (fig. 475) envelops the joint, and is attached, above, to the circumference of the glenoid cavity beyond the glenoidal labrum; below, to the anatomical neck of the humerus, approaching nearer to the articular cartilage at the upper than at the lower part of the neck. It is thicker above and below than elsewhere, and is so remarkably loose and lax, that the bones may be separated from each other for a distance of about 2.5 cm., an evident provision for the great freedom of movement which is permitted at this articulation. It is strengthened, above, by the Supraspinatus; below, by the long head of the Triceps brachii; behind, by the tendons of the Infraspinatus and Teres minor; and in front, by the tendon of the Subscapularis. There are usually three openings in the capsule. One anteriorly, below the coracoid process, establishes a communication between the joint and a bursa beneath the tendon of the Subscapularis; another, between the tubercles of the humerus, gives passage to the long tendon of the Biceps brachii; the third, which is not constant, is at the posterior part, between the joint and a bursal sac under the tendon of the Infraspinatus.

Three supplemental bands, which are named the *glenohumeral ligaments*, strengthen the capsule. These are best seen by opening the posterior part of the capsule of the joint and removing the head of the humerus. One on the medial side of the joint passes from the medial edge of the glenoid cavity to the lower part of the lesser tubercle of the humerus; a second at the lower part of the joint extends from the under edge of the glenoid cavity to the under part of the anatomical neck; a third at the upper part of the joint is fixed above to the apex of the glenoid cavity close to the root of the coracoid process, and passing downwards along the medial edge of the tendon of the Biceps brachii, is attached below to a small depression above the lesser tubercle. In addition to these, the capsule is strengthened in front by two bands, one derived from the tendon of the Pectoralis major, the other from the tendon of the Teres major.

The **synovial stratum** is reflected from the margin of the glenoid cavity over the labrum; it is then reflected over the inner surface of the capsule, and covers the lower part and sides of the anatomical neck of the humerus as far as the articular cartilage on the head of the bone. The tendon of the long head of the Biceps brachii passes through the fibrous stratum of the capsule and is enclosed in a tubular sheath of the synovial stratum, which is reflected upon it from the summit of the glenoid cavity and is continued round the tendon into the intertubercular sulcus as far as the surgical neck of the humerus (fig. 476).

The **coracohumeral ligament** is a broad band which strengthens the upper part of the capsule. It arises from the lateral border of the root of the coracoid process, and passes obliquely downwards and lateralwards to the front of the greater tubercle of the humerus, blending with the tendon of the Supraspinatus. The hinder and lower border of the ligament is united to the capsule; its anterior and upper border is free, and overlaps the capsule.

The **transverse humeral ligament** (fig. 475) is a broad band passing from the lesser to the greater tubercle of the humerus; it converts the intertubercular sulcus into a canal, and its attachment is always limited to that portion of the bone which lies above the epiphysial line.

FIG. 475.—Articular capsule of shoulder-joint (distended). Anterior aspect.

The **glenoidal labrum** (glenoid ligament) is a fibrocartilaginous rim attached round the margin of the glenoid cavity. It is triangular on section, the base being fixed to the circumference of the cavity, while the free edge is thin and sharp. It is continuous above with the tendon of the long head of the Biceps brachii, which gives off two fasciculi to blend with the fibrous tissue of the labrum. It deepens the articular cavity, and protects the edges of the bone.

Bursæ.—The bursæ in the neighbourhood of the shoulder-joint are the following: (1) One is constantly found between the tendon of the Subscapularis muscle and the capsule: it communicates with the synovial cavity through an opening in the front of the capsule; (2) one is sometimes found between the tendon of the Infraspinatus and the capsule; it occasionally opens into the joint; (3) a large one exists between the under surface of the Deltoides and the capsule, but does not communicate with the joint: this bursa is prolonged under the acromion and coraco-acromial ligament, and intervenes between these structures and the capsule; (4) a large one is situated on the summit of the acromion; (5) one is frequently found between the coracoid process and the capsule; (6) one exists beneath the Coracobrachialis; (7) one lies between the Teres major and the long head of the Triceps brachii; (8) one is placed in front of, and another behind, the tendon of the Latissimus dorsi.

The **muscles** in relation with the joint are, above, the Supraspinatus; below, the long head of the Triceps brachii; in front, the Subscapularis; behind, the

Infraspinatus and Teres minor; within, the tendon of the long head of the Biceps brachii. The Deltoideus covers the articulation in front, behind, and laterally.

The *arteries* supplying the joint are derived from the anterior and posterior humeral circumflex, and transverse scapular arteries; the *nerves*, from the axillary and suprascapular nerves.

Movements.—The shoulder-joint is capable of flexion, extension, abduction, adduction, circumduction, and rotation. The humerus is *flexed* (drawn forwards) by the Pectoralis major, anterior fibres of the Deltoideus, Coracobrachialis, and when the forearm is flexed, by the Biceps brachii; *extended* (drawn backwards) by the Latissimus dorsi, Teres major, posterior fibres of the Deltoideus, and, when the forearm is extended, by the Triceps brachii; it is *abducted* by the Deltoideus and Supraspinatus; it is *adducted* by the Subscapularis, Pectoralis major, Latissimus dorsi, and Teres major, and by the weight of the limb; it is *rotated outwards* by the Infraspinatus and Teres minor; and it is *rotated inwards* by the Subscapularis, Latissimus dorsi, Teres major, Pectoralis major, and the anterior fibres of the Deltoideus.

The most striking peculiarities in this joint are: 1. The large size of the head of the humerus in comparison with the depth of the glenoid cavity, even though this latter is supplemented by the glenoidal labrum. 2. The looseness of the capsule of the joint. 3. The intimate connexion of the capsule with the muscles attached to the head of the humerus. 4. The peculiar relation of the tendon of the long head of the Biceps brachii to the joint.

It is in consequence of the relative sizes of the two articular surfaces, and the looseness of the articular capsule, that the joint enjoys such free movement in all directions. When these movements of the arm are arrested in the shoulder-joint by the contact of the bony surfaces, and by the tension of the fibres of the capsule together with that of the muscles acting as accessory ligaments, the arm can be carried considerably farther by the movements of the scapula, involving, of course, motion at the sternoclavicular and acromioclavicular joints. These joints are therefore to be regarded as accessory to the shoulder-joint (see pp. 365 to 368). The extent of the scapular movements is very considerable, especially in extreme elevation of the arm, a movement best accomplished when the arm is thrown somewhat forwards and outwards, because the margin of the head of the humerus is by no means a true circle; the greatest diameter of the head is from the intertubercular groove, downwards, medialwards, and backwards, and the greatest elevation of the arm can be obtained by rolling its articular surface in the direction of this measurement.

The looseness of the capsule is so great that the arm will fall about 2.5 cm. from the scapula when the muscles are dissected from the capsule, and an opening made in it to counteract the atmospheric pressure. The movements of the joint, therefore, are not regulated by the capsule so much as by the surrounding muscles, an arrangement which 'renders the movements of the joint much more easy than they would otherwise have been, and permits a swinging, pendulum-like vibration of the limb when the muscles are at rest' (Humphry). The fact, also, that in all ordinary positions of the joint the capsule is not put on the stretch, enables the arm to move freely in all directions. Some movements are checked by the tension of appropriate portions of the capsule, as well as by the interlocking of the bones. Thus it is said that 'abduction is checked by the contact of the great tuberosity with the upper edge of the glenoid cavity; adduction by the tension of the coracohumeral ligament' (Beaunis and Bouchard). Cleland* maintains that the limitations of movement at the shoulder-joint are due to the structure of the joint itself, the glenoidal labrum fitting, in different positions of the elevated arm, into the anatomical neck of the humerus.

The scapula is capable of being moved upwards and downwards, and forwards and backwards, and, by a combination of these movements, circumducted on the wall of the chest. The muscles which *raise* the scapula are the upper fibres of the Trapezius, the Levator scapulæ, and the Rhomboidei; those which *depress* it are the lower fibres of the Trapezius, the Pectoralis minor, and, through the clavicle, the Subclavius. The scapula is drawn *backwards* by the Rhomboidei and the middle and lower fibres of the Trapezius, and *forwards* by the Serratus anterior and Pectoralis minor, assisted, when the arm is fixed, by the Pectoralis major. The mobility of the scapula is very considerable, and greatly assists the movements of

* *Journal of Anatomy and Physiology*, vol. i., 1867.

the arm at the shoulder-joint. Thus, in raising the arm from the side, the Deltoides and Supraspinatus can only lift it to a right angle with the trunk, the farther elevation of the limb being effected by the Trapezius and Serratus anterior moving the scapula on the wall of the chest. This mobility is of special importance in ankylosis of the shoulder-joint, the movements of the scapula compensating to a very great extent for the immobility of the joint.

Cathcart* has pointed out that in abducting the arm and raising it above the head, the scapula rotates throughout the whole movement with the exception of a short space at the beginning and at the end; that the humerus moves on the scapula not only while passing from the hanging to the horizontal position, but also in travelling upwards as it approaches the vertical above; that the clavicle moves not only during the second half of the movement but in the first as well, though to a less extent—i.e. the scapula and clavicle are concerned in the first stage as well as in the second; and that the humerus is partly involved in the second as well as chiefly in the first.

The peculiar relations of the tendon of the long head of the Biceps brachii to the shoulder-joint appear to subserve various purposes. In the first place, by its connexion with both the shoulder and elbow the muscle harmonises the action of the two joints, and acts as an elastic ligament in all positions, in the manner previously discussed (see p. 345). It strengthens the upper part of the articular cavity, and prevents the head of the humerus from being pressed up against the acromion when the Deltoides contracts; it thus fixes the head of the humerus as the centre of motion in the glenoid cavity. By its passage along the intertubercular sulcus it assists in steadying the head of the humerus in the various movements of the arm. When the arm is raised from the side the Biceps brachii assists the Supraspinatus and Infraspinatus in rotating the head of the humerus in the glenoid cavity. It also holds the head of the bone firmly in contact with the glenoid cavity, and prevents it slipping over the lower edge, or being displaced by the action of the Latissimus dorsi and Pectoralis major, as in climbing and many other movements.

Applied Anatomy.—Owing to the construction of the shoulder-joint and the freedom of movement which it enjoys, as well as in consequence of its exposed situation, it is more frequently dislocated than any other joint. Dislocation occurs when the arm is abducted, and when, therefore, the head of the humerus presses against the lower and front part of the capsule, which is the thinnest and least supported part of the ligament. The rent in the capsule almost invariably takes place in this situation, and through it the head of the bone escapes, so that the dislocation in most instances is primarily subglenoid. The head of the bone does not usually remain in this situation, between the tendons of the Subscapularis and the Triceps brachii, but generally assumes some other position; which varies according to the direction and amount of force producing the dislocation and the relative strength of the muscles in front of and behind the joint. As the muscles at the back are stronger than those in front, and especially since the long head of the Triceps brachii prevents the bone from passing backwards, dislocation forwards is much the more common. The most frequent position which the head of the humerus ultimately assumes is on the front of the neck of the scapula, beneath the coracoid process, and hence named subcoracoid. Occasionally, in consequence of a greater amount of force being brought to bear on the limb, the head is driven farther medialwards, and rests on the upper part of the front of the chest, beneath the clavicle (subclavicular). Sometimes it remains in the position in which it was primarily displaced, resting on the axillary border of the scapula (subglenoid), and rarely it passes backwards and remains in the infraspinatus fossa, beneath the spine (subspinous).

The shoulder-joint may be the seat of any of those inflammatory affections, either acute or chronic, which attack joints, though perhaps less frequently than some other articulations of equal size and importance. Acute synovitis may result from injury, rheumatism, or pyæmia, or may follow secondarily on acute epiphysitis in infants. It is attended with effusion into the joint, and when this occurs the capsule is evenly distended, and the contour of the joint rounded. Special projections may occur at the sites of the openings in the capsule. Thus a swelling may appear just medial to the lesser tubercle, from effusion into the bursa beneath the Subscapularis; or, again, a swelling which is sometimes bilobed may be seen in the interval between the Deltoides and Pectoralis major, from effusion into the diverticulum which runs down the intertubercular groove with the tendon of the Biceps brachii. The effusion into the joint-cavity can be best ascertained by examination from the axilla, where a soft, elastic, fluctuating swelling can usually be felt. In cases of septic synovitis, where incision is required, the opening should be made in front, over the most prominent point of the swelling. After the

* *Journal of Anatomy and Physiology*, 1884, vol. xviii.

pus has been evacuated a counter-opening should be made behind, so as to ensure efficient drainage.

Tuberculous arthritis not infrequently attacks the shoulder-joint, and may lead to total destruction of the articulation, when ankylosis may result, or long-protracted suppuration may necessitate excision. This joint is also one of those which is most liable to be the seat of osteo-arthritis, and may also be affected in gout and rheumatism; or in locomotor ataxy, when it becomes the seat of Charcot's disease.

Ankylosis is occasionally met with in the shoulder-joint as the result of destructive changes. The ankylosis usually takes place with the arm in a dependent position, and any attempt to raise the arm is attended by a rotation of the scapula on the wall of the chest.

Excision of the shoulder-joint may be required in cases of arthritis (especially the tuberculous form) which have gone on to destruction of the articulation; in compound dislocations and fractures, particularly those arising from gunshot injuries, in which there has been extensive injury to the head of the bone; in some cases of old unreduced dislocation, where there is much pain. The operation is best performed by making an incision from the middle of the coraco-acromial ligament down the arm for about 7 or 8 cm.; this will expose the intertubercular groove containing the tendon of the Biceps brachii, which should be hooked out of the way. The capsule is freely opened, and the muscles attached to the greater and lesser tubercles of the humerus are stripped off with the capsule, without dividing their attachments to the latter. The head of the bone can then be thrust out of the wound and sawn off; or divided with a narrow saw *in situ* and subsequently removed. The section should be made, if possible, just below the articular surface, so as to leave the bone as long as possible.

IV. CUBITAL ARTICULATION OR ELBOW-JOINT

The elbow-joint (figs. 478, 479) includes three articulations:—(1) *humero-ulnar*, between the trochlea of the humerus and the semilunar notch of the ulna, (2) *humero-radial*, between the capitulum of the humerus and the fovea on the head of the radius, and (3) *proximal radio-ulnar*, where the circumference of the radial head is retained in the circle formed by the annular ligament and the radial notch of the ulna (see p. 376). All three are included in a common articular capsule.

The humero-ulnar and humero-radial articulations together form a ginglymus or hinge-joint, the ligaments of which are:

The articular capsule.

Ulnar collateral.

Radial collateral.

Articular capsule.—The anterior part of the articular capsule is a broad and thin fibrous layer. It is attached, above, to the front of the medial epicondyle and to the front of the humerus immediately above the coronoid and radial fossæ; below, to the anterior surface of the coronoid process of the ulna and to the annular ligament (p. 376), being continuous on either side with the collateral ligaments. Its superficial fibres pass obliquely from the medial epicondyle of the humerus to the annular ligament. The middle fibres, vertical in direction, pass from the upper part of the coronoid depression and become partly blended with the preceding, but are inserted mainly into the anterior surface of the coronoid process. The deep or transverse set intersects these at right angles. It is in relation, in front, with the Brachialis, except at its most lateral part.

The posterior part of the articular capsule is thin and membranous, and consists of transverse and oblique fibres. Above, it is attached to the humerus immediately behind the capitulum and close to the medial margin of the trochlea, to the margins of the olecranon fossa, and to the back of the lateral epicondyle some little distance from the trochlea. Below, it is fixed to the upper and lateral margins of the olecranon, to the posterior part of the annular ligament, and to the ulna behind the radial notch. The transverse fibres form a strong fasciculus which bridges the olecranon fossa; under cover of this band a pouch of the synovial stratum and a pad of fat are displaced into the upper part of the fossa when the joint is extended. In the fat are a few scattered fibrous bundles which pass from the deep surface of the transverse band to the upper part of the fossa. It is in relation, behind, with the tendon of the Triceps brachii and the Anconæus.

The *synovial stratum* (figs. 476, 477) is very extensive. It extends from the margin of the articular surface of the humerus, and lines the coronoid,

radial and olecranon fossæ on that bone ; it is reflected over the deep surface of the capsule and lines the deep surface of the annular ligament. Projecting into the joint-cavity between the radius and ulna is a crescentic fold of the synovial stratum, suggesting the division of the joint into two : one the humero-radial, the other the humero-ulnar.

Between the fibrous and the synovial strata of the articular capsule are three masses of fat. The largest, over the olecranon fossa, is pressed into the fossa by the *Triceps brachii* during flexion ; the second, over the coronoid fossa, and the third, over the radial fossa, are pressed by the *Brachialis* into their respective fossæ during extension.

FIG. 476.—Articular capsule of elbow-joint (distended). Anterior aspect.

FIG. 477.—Articular capsule of elbow-joint (distended). Posterior aspect.

The ulnar collateral ligament (internal lateral ligament) (fig. 478) is a thick triangular band consisting of two portions, an anterior and a posterior, united by a thinner intermediate portion. The *anterior portion*, directed obliquely forwards, is attached, above, by its apex, to the front part of the medial epicondyle of the humerus ; and, below, by its broad base, to the medial margin of the coronoid process. The *posterior portion*, also of triangular form, is attached, above, by its apex, to the lower and back part of the medial epicondyle ; below, to the medial margin of the olecranon. Between these two bands a few intermediate fibres descend from the medial epicondyle to an *oblique band* which stretches between the olecranon and coronoid processes and converts the depression on the medial margin of the semilunar notch into a foramen, through which the intra-articular pad of fat is continuous with the extra-articular fat on the medial side of the joint. The ulnar collateral

FIG. 478.—Left elbow-joint, from medial side.

FIG. 479.—Left elbow-joint, from lateral side.

ligament is in relation with the *Triceps brachii* and *Flexor carpi ulnaris* and the ulnar nerve, and gives origin to part of the *Flexor digitorum sublimis*.

The **radial collateral ligament** (external lateral ligament) (fig. 479), a short and narrow fibrous band, less distinct than the ulnar collateral, is attached, above, to a depression below the lateral epicondyle of the humerus, and below, to the annular ligament; some of its most posterior fibres pass over that ligament, to be inserted into the lateral margin of the ulna. It is intimately blended with the origins of the *Supinator* and *Extensor carpi radialis brevis*.

The *muscles* in relation with the joint are, in front, the *Brachialis*; behind, the *Triceps brachii* and *Anconæus*; laterally, the *Supinator*, and the common tendon of origin of the extensor muscles; medially, the common tendon of origin of the flexor muscles, and the *Flexor carpi ulnaris*.

The *arteries* supplying the joint are derived from the anastomosis between the *profunda* and the superior and inferior ulnar collateral branches of the brachial, with the anterior, posterior, and interosseous recurrent branches of the ulnar, and the recurrent branch of the radial. These vessels form an anastomotic network around the joint.

The *nerves* of the joint are a twig from the ulnar, as it passes between the medial condyle and the olecranon; a filament from the musculocutaneous, and two from the median.

The movements at the elbow-joint are described on p. 378.

V. RADIO-ULNAR ARTICULATIONS

The articulation of the radius with the ulna is effected by ligaments which connect together the extremities and also the bodies of these bones. The ligaments may, consequently, be subdivided into three sets: 1, those of the proximal radio ulnar articulation; 2, the middle radio-ulnar ligaments; 3, those of the distal radio-ulnar articulation.

1. PROXIMAL RADIO-ULNAR ARTICULATION

This articulation forms a trochoid or pivot-joint between the circumference of the head of the radius and the ring formed by the radial notch of the ulna and the annular ligament.

The **annular ligament** (orbicular ligament) (figs. 476, 477, 480) is a strong band of fibres, which encircles the head of the radius, and retains it in contact with the radial notch of the ulna. It forms about four-fifths of the osseofibrous ring and is attached to the anterior and posterior margins of the radial notch; a few of its lower fibres are continued round below the notch and form at this level a complete fibrous ring. Its upper border blends with the anterior and posterior parts of the articular capsule of the elbow-joint, while from its lower border a thin loose membrane passes to be attached to the neck of the radius. A thickened band which extends from the inferior border of the annular ligament below the radial notch to the neck of the radius is known as the *quadrate ligament*. The *superficial surface* of the annular ligament is strengthened by the radial collateral ligament of the elbow, and affords origin to part of the *Supinator*. Its *deep surface* is lined by a synovial stratum which is continuous with that of the elbow-joint.

Movements.—The movements allowed in this articulation are limited to rotatory movements of the head of the radius within the ring formed by the annular ligament and the radial notch of the ulna; rotation forwards being called *pronation*; rotation backwards, *supination*. Pronation is performed by the *Pronator teres* and *Pronator quadratus*; supination by the *Biceps brachii* and *Supinator*, assisted to a slight extent by the *Extensor* muscles of the thumb.

2. MIDDLE RADIO-ULNAR UNION

The bodies of the radius and ulna are connected by the oblique cord and the antibrachial interosseous membrane.

The **oblique cord** (fig. 478) is a small, flattened band, extending from the lateral side of the tubercle of the ulna at the base of the coronoid process to the radius a little below the radial tuberosity. Its fibres run in the opposite direction to those of the interosseous membrane. It is sometimes wanting.

The **antibrachial interosseous membrane** is a broad and thin sheet of fibrous tissue, the fibres of which slant obliquely downwards and medialwards, from the interosseous crest of the radius to that of the ulna; the lower part of the membrane is attached to the posterior of the two lines into which the interosseous crest of the radius divides. Two or three fibrous bands are occasionally found on the dorsal surface of this membrane; they descend obliquely from the ulna towards the radius, i.e. in a direction contrary to that of the other fibres. It is deficient above, commencing about 2.5 cm. below

FIG. 480.—Annular ligament of radius, from above. The head of the radius has been sawn off and the bone dislodged from the ligament.

the tuberosity of the radius; is broader in the middle than at either end; and presents an oval aperture a little above its lower margin, for the passage of the volar interosseous vessels to the back of the forearm. Between its upper border and the oblique cord is a gap, through which the dorsal interosseous vessels pass. This membrane serves to connect the bones, and to increase the extent of surface for the attachment of the deep muscles. It also transmits to the ulna and thence to the humerus any force acting upwards through the hand and radius. It is relaxed in complete pronation or supination, and is most tense when the hand is midway between the prone and supine positions. The membrane is in relation, *in front*, by its upper three-fourths, with the Flexor pollicis longus on the radial side, and with the Flexor digitorum profundus on the ulnar side; between these muscles are the volar interosseous vessels and nerve; by its lower fourth with the Pronator quadratus; *behind*, with the Supinator, Abductor pollicis longus, Extensor pollicis brevis, Extensor pollicis longus, Extensor indicis proprius; and, near the wrist, with the volar interosseous artery and dorsal interosseous nerve.

3. DISTAL RADIO-ULNAR ARTICULATION

This is a pivot-joint formed between the head of the ulna and the ulnar notch of the lower end of the radius; the surfaces are enclosed in an articular capsule and held together by an articular disc.

The **articular capsule** is slightly thickened in front and behind; above, it is lax and, with the synovial stratum, projects upwards as a pouch (*recessus sacciformis*) between the radius and the ulna.

The **articular disc** (fig. 483) is triangular in shape, and is placed distally to the head of the ulna, binding the lower ends of the ulna and radius firmly together. Its periphery is thicker than its centre, which is occasionally perforated. It is attached by its apex to a depression between the styloid process and the head of the ulna; and by its base, which is thin, to the prominent edge of the radius which separates the ulnar notch from the carpal articular surface. Its margins are united to the ligaments of the wrist-joint. Its *proximal surface*, smooth and concave, articulates with the head of the ulna, forming an arthrodial joint; its *distal surface*, also concave and smooth, forms part of the radiocarpal joint and articulates with the triquetral bone and medial part of the lunate bone. Each of its surfaces is clothed by a synovial stratum: the proximal, by that of the distal radio-ulnar articulation; the distal, by that of the radiocarpal joint.

Movements.—The movements of the three joints within the elbow should be studied together. The combination of the movements of flexion and extension of the forearm with those of pronation and supination of the hand, which is ensured by the two being performed at the same joint, is essential to the accuracy of the various minute movements of the hand.

The portion of the joint between the ulna and humerus is a simple hinge-joint, and allows of movements of flexion and extension only. Owing to the obliquity of the trochlea of the humerus, this movement does not take place in the antero-posterior plane of the body of the humerus. When the forearm is extended and supinated, the axes of the arm and forearm are not in the same line; the arm forms an obtuse angle with the forearm, the hand and forearm being directed laterally. During flexion, however, the forearm and the hand tend to approach the middle line of the body, and thus enable the hand to be easily carried to the face. The accurate adaptation of the trochlea of the humerus, with its prominences and depressions, to the semilunar notch of the ulna, prevents any lateral movement. *Flexion* is produced by the Biceps brachii and Brachialis, assisted by the Brachioradialis and the muscles arising from the medial condyle of the humerus; *extension* by the Triceps brachii and Anconæus, assisted by the Extensors of the wrist, the Extensor digitorum communis, and the Extensor digiti quinti proprius.

The joint between the head of the radius and the capitulum of the humerus is an arthrodial joint. The bony surfaces would of themselves constitute an enarthrosis and allow of movement in all directions, were it not for the annular ligament, by which the head of the radius is bound to the radial notch of the ulna, and which prevents any separation of the two bones laterally. It is to the same ligament that the head of the radius owes its security from dislocation, which would otherwise tend to occur, from the shallowness of the cup-like surface on the head of the radius. In fact, but for this ligament, the tendon of the Biceps brachii would be liable to pull the head of the radius out of the joint. The head of the radius is not in complete contact with the capitulum of the humerus in all positions of the joint. The capitulum occupies only the anterior and inferior surfaces of the lower end of the humerus, so that in complete extension a part of the radial head can be plainly felt projecting at the back of the articulation. In full flexion the movement of the radial head is hampered by the compression of the surrounding soft parts, so that the freest rotatory movement of the radius on the humerus (pronation and supination) takes place in semiflexion, in which position the two articular surfaces are in most intimate contact. Flexion and extension of the elbow-joint are limited by the tension of the structures on the front and back of the joint; the limitation of flexion is also aided by the soft structures of the arm and forearm coming into contact.

In any position of flexion or extension, the radius, carrying the hand with it, can be rotated in the proximal radio-ulnar joint. The hand is directly articulated to the lower surface of the radius only, and the ulnar notch on the lower end of the radius travels round the lower end of the ulna. The latter bone is excluded from the wrist-joint by the articular disc. Thus, rotation of the head of the radius round an axis passing through the centre of the radial head of the humerus imparts circular movement to the hand through a very considerable arc.

The movements in the distal radio-ulnar articulation consist of rotation of the lower end of the radius round an axis which passes through the centre of the head of the ulna. When the radius rotates forwards, *pronation* of the forearm and hand is the result; and when backwards, *supination*. It will thus be seen that in

pronation and supination the radius describes the segment of a cone, the axis of which extends from the centre of the head of the radius to the middle of the head of the ulna. In this movement the head of the ulna is not stationary, but describes a curve in a direction opposite to that taken by the head of the radius. This, however, is not to be regarded as a rotation of the ulna—the curve which the head of this bone describes is due to a combined anteroposterior and rotatory movement, the former taking place almost entirely at the elbow-joint, the latter at the shoulder-joint.

Applied Anatomy.—From the breadth of the elbow-joint, and the manner in which the articular surfaces are interlocked, and also on account of the strong collateral ligaments and the support which the joint derives from the mass of muscles attached to each epicondyle of the humerus, lateral displacement of the bones is very uncommon; whereas anteroposterior dislocation, on account of the shortness of the anteroposterior diameter, the weakness of the anterior and posterior parts of the articular capsule, and the want of support of muscles, occurs much more frequently. Dislocation backwards takes place when the forearm is in a position of extension, and forwards when in a position of flexion. For, in the extended position, the coronoid process is not locked into the coronoid fossa, and loses its grip to a certain extent, whereas the olecranon is in the olecranon fossa, and entirely prevents displacement forwards. On the other hand, during flexion, the coronoid process is in the coronoid fossa, and prevents dislocation backwards, while the olecranon, having left the olecranon fossa, is not so efficient in preventing a forward displacement. When lateral dislocation does take place it is generally incomplete. Dislocation of the elbow-joint is of common occurrence in children, far more common than dislocation of any other articulation. As a rule, in young persons, the application of any severe violence to a joint is more likely to produce a fracture of bone than dislocation. In lesions of this joint there is often very great difficulty in ascertaining the exact nature of the injury.

The elbow-joint is occasionally the seat of acute synovitis. The joint-cavity then becomes distended with fluid, the bulging showing itself principally around the olecranon, in consequence of the laxness of the articular capsule. Again, there is often some swelling just above the head of the radius, in the line of the radiohumeral joint, or the whole elbow may assume a fusiform appearance. There is not generally much swelling at the front of the joint, though sometimes deep-seated fulness beneath the *Brachialis* may be noted. When suppuration occurs the abscess usually points at one or other border of the *Triceps brachii*; occasionally the pus discharges itself in front, near the insertion of the *Brachialis*. In cases of suppurative synovitis, incisions should be made into the joint on either side of the olecranon, care being taken to avoid wounding the ulnar nerve on the medial side. Chronic synovitis, usually of tuberculous origin, is of common occurrence in the elbow-joint; in such cases the forearm tends to assume the position of semiflexion, which is that of greatest ease and relaxation of ligaments. It should be borne in mind that if ankylosis occur in this or the extended position, the limb will not be nearly so useful as if ankylosed in a position of rather less than a right angle. The elbow-joint is also sometimes affected with osteo-arthritis, but less commonly than some of the larger joints.

Excision of the elbow is principally required for one of three conditions—viz. tuberculous arthritis, injury and its results, or faulty ankylosis—but may be necessary for some other rarer conditions, such as disorganising arthritis after pyæmia and unreduced dislocations. The results of the operation are, as a rule, more favourable than those of excision of any other joint, especially in any of the first three conditions mentioned above. The operation is best performed by a vertical incision down the back of the joint; a straight incision is made about 10 cm. long, the mid-point of which is on a level with and a little to the medial side of the tip of the olecranon. This incision is made down to the bone, through the substance of the *Triceps brachii*. The operator, guarding the soft parts with his thumb-nail, separates them from the bone with the point of his knife. In doing this there are two structures which he should carefully avoid: the ulnar nerve, which as it courses down between the medial epicondyle and the olecranon lies parallel but a little medially to his incision; and the prolongation of the *Triceps brachii* into the deep fascia of the forearm over the *Anconeus*. After clearing the bones and dividing the collateral and posterior ligaments, the forearm should be strongly flexed and the ends of the bones turned out and sawn off. The turning out of the ends of the bones is rendered easier by first cutting off the olecranon with a pair of cutting bone forceps. The section of the humerus should be through the base of the epicondyles, that of the ulna and radius should be just below the level of the radial notch of the ulna and the neck of the radius. In this operation the object is to obtain such union as shall allow free motion of the bones of the forearm; and, therefore, passive movements must be commenced early—that is to say, about the tenth day. It is most important to maintain the continuity of the *Triceps brachii* with the deep fascia of the forearm, so as to obtain good power of extension in the new joint.

Dislocation of the head of the radius alone is a not uncommon accident, and occurs most frequently in young persons from falls on the hand when the forearm is extended and supinated, the head of the bone being displaced forward. It is attended by rupture

of the annular ligament. Occasionally a peculiar injury, which is supposed to be a subluxation, occurs in young children in lifting them from the ground by the hand or forearm. It is believed that the head of the radius is displaced downwards in the annular ligament, the upper border of which becomes folded over the head of the radius, between it and the capitulum of the humerus. The forearm becomes fixed in a position of semiflexion, midway between supination and pronation, and great pain is complained

FIG. 481.—Ligaments of wrist and metacarpus. Anterior view.

of upon any attempt to move the joint. The synovial stratum of the proximal radio-ulnar joint is directly continuous with that of the elbow-joint, and, therefore, any septic or tuberculous disease which affects the latter also involves the former joint. The proximal radio-ulnar joint is always removed in an excision of the elbow (see preceding paragraph).

VI. RADIOCARPAL ARTICULATION OR WRIST-JOINT

The radiocarpal articulation or wrist-joint (figs. 481, 482) is a condyloid articulation. The parts forming it are the distal end of the radius and under surface of the articular disc above; and the navicular, lunate, and triquetral bones below. The articular surface of the radius and the under surface of the

articular disc form together a transversely elliptical concave surface, the *receiving cavity*. The proximal articular surfaces of the navicular, lunate, and triquetral bones form a smooth convex surface, the *condyle*, which is received into the concavity. The joint is surrounded by an **articular capsule**. The *synovial stratum* of the capsule is usually distinct from that of the distal radio-ulnar joint and from that of the carpal joints; the *fibrous stratum* is strengthened by the following ligaments:

Volar radiocarpal.
Dorsal radiocarpal.

Ulnar collateral.
Radial collateral.

The **volar radiocarpal ligament** (fig. 481) is a broad membranous band, attached above to the anterior margin of the distal end of the radius, to its styloid process, and to the front of the distal end of the ulna; its fibres pass

FIG. 482.—Ligaments of wrist. Posterior view.

downwards and medialwards to be attached to the volar surfaces of the navicular, lunate, and triquetral bones, some being continued to the capitate bone. In addition to this broad membrane, there is a rounded fasciculus, superficial to the rest, which reaches from the base of the styloid process of the ulna to the lunate and triquetral bones. The ligament is perforated by apertures for the passage of vessels, and is in relation, in front, with the tendons of the Flexor digitorum profundus and Flexor pollicis longus; behind, it is closely adherent to the anterior border of the articular disc of the distal radio-ulnar articulation.

The **dorsal radiocarpal ligament** (fig. 482), less thick and strong than the volar, is attached, above, to the posterior border of the distal end of the radius; its fibres are directed obliquely downwards and medialwards, and are fixed, below, to the dorsal surfaces of the navicular, lunate, and triquetral bones, being continuous with those of the dorsal intercarpal ligaments. It is in relation, behind, with the Extensor tendons of the fingers; in front, it is blended with the articular disc of the distal radio-ulnar articulation.

The **ulnar collateral ligament** (internal lateral ligament) (fig. 481) is attached above to the end of the styloid process of the ulna, and divided below into two fasciculi, one of which is attached to the medial side of the triquetral bone, the other to the pisiform bone.

The **radial collateral ligament** (external lateral ligament) (fig. 481) extends from the tip of the styloid process of the radius to the radial side of the navicular bone, some of its fibres being prolonged to the greater multangular bone. It is in relation with the radial artery, which separates the ligament from the tendons of the *Abductor pollicis longus* and *Extensor pollicis brevis*.

The *arteries* supplying the joint are the volar interosseous, the volar and dorsal carpal branches of the radial and ulnar, the volar and dorsal metacarpals, and some recurrent branches from the deep volar arch. The *nerves* are derived from the ulnar and dorsal interosseous nerves.

Movements.--The movements permitted in this joint are flexion, extension, abduction, adduction, and circumduction. They will be studied with those of the carpus, with which they are combined.

VII. INTERCARPAL ARTICULATIONS

These articulations may be subdivided into three sets: (1) those of the proximal row of carpal bones; (2) those of the distal row of carpal bones; and (3) those of the two rows with each other.

1. ARTICULATIONS OF THE PROXIMAL ROW OF CARPAL BONES

These are arthrodial joints. The navicular, lunate, and triquetral are connected by dorsal, volar, and interosseous ligaments.

The **dorsal and volar ligaments**, two of each, are placed transversely between the bones of the first row; they connect the navicular and lunate bones, and the lunate and triquetral bones. The volar ligaments are weaker than the dorsal.

The **interosseous ligaments** (fig. 483) are two narrow bundles, one connecting the lunate bone with the navicular bone, the other joining the lunate bone to the triquetral bone. They are on a level with the proximal surfaces of these bones, and their proximal ends are smooth, and form part of the convex articular surface of the radiocarpal joint.

The ligaments of the pisiform bone are an articular capsule, the pisohamate and the pisometacarpal ligaments.

The **articular capsule** is thin and connects the pisiform to the triquetral. Its synovial stratum is distinct from that of the other carpal joints.

The **pisohamate ligament** connects the pisiform bone to the hamate bone, and the **pisometacarpal ligament** joins the pisiform bone to the base of the fifth metacarpal bone (fig. 481). These two ligaments are, in reality, prolongations of the tendon of the *Flexor carpi ulnaris*.

2. ARTICULATIONS OF THE DISTAL ROW OF CARPAL BONES

These also are arthrodial joints; the bones are connected by dorsal, volar, and interosseous ligaments.

The **dorsal and volar ligaments**, each three in number, extend transversely from one bone to another; one connects the greater and lesser multangular bones, a second the lesser multangular and capitate bones, and a third the capitate and hamate bones.

The three **interosseous ligaments** are much thicker than those of the proximal row; one unites the capitate and hamate bones, a second the capitate and lesser multangular bones, and a third the greater and lesser multangular bones. The first is the strongest; the third is sometimes wanting.

3. ARTICULATIONS OF THE TWO ROWS OF CARPAL BONES WITH EACH OTHER

The joint between the navicular, lunate, and triquetral bones on the one hand, and the second row of carpal bones on the other, is named the *mid-carpal joint*, and is made up of three portions: in the centre the head of the capitate

Movements.—The articulation of the hand and forearm considered as a whole involves four articular surfaces: (a) the inferior surfaces of the radius and articular disc; (b) the superior surfaces of the navicular, lunate, and triquetral bones, the pisiform bone having no essential part in the movement of the hand; (c) the S-shaped surface formed by the inferior surfaces of the navicular, lunate, and triquetral bones; (d) the reciprocal surface formed by the upper surfaces of the bones of the second row. These four surfaces form two joints: (1) a proximal, the radiocarpal; and (2) a distal, the mid-carpal joint.

(1) The radiocarpal joint is a true condyloid articulation, and therefore all movements but rotation are permitted. Flexion and extension are the most free, and of these a greater amount of extension than of flexion is permitted, since the articulating surfaces extend farther on the dorsal than on the volar surfaces of the carpal bones. In this movement the carpal bones rotate on a transverse axis drawn between the tips of the styloid processes of the radius and ulna. Adduction or ulnar flexion, and abduction or radial flexion are also permitted. The former is considerably greater in extent than the latter on account of the shortness of the styloid process of the ulna, abduction being soon limited by the contact of the styloid process of the radius with the greater multangular bone. In this movement the carpus revolves upon an anteroposterior axis drawn through the centre of the wrist.* Finally, circumduction is permitted by the combined and consecutive movements of adduction, extension, abduction, and flexion. No rotation is possible, but the effect of rotation is obtained by the pronation and supination of the radius on the ulna. The movement of *flexion* is performed by the Flexor carpi radialis, the Flexor carpi ulnaris, and the Palmaris longus; *extension* by the Extensores carpi radiales longus and brevis and the Extensor carpi ulnaris; *adduction* (ulnar flexion) by the Flexor carpi ulnaris and the Extensor carpi ulnaris; and *abduction* (radial flexion) by the Abductor pollicis longus, the Extensors of the thumb, and the Extensores carpi radiales longus and brevis and the Flexor carpi radialis. When the fingers are extended, flexion of the wrist is performed by the Flexores carpi radialis and ulnaris and extension by the Extensor digitorum communis. When the fingers are flexed, flexion of the wrist is performed by the Flexores digitorum sublimis and profundis, and extension by the Extensores carpi radiales and ulnaris.

(2) The chief movements permitted in the mid-carpal joint are flexion and extension and a slight amount of rotation. In flexion and extension, which are the movements most freely enjoyed, the greater and lesser multangular bones on the radial side and the hamate bone on the ulnar side glide forwards and backwards on the navicular and triquetral bones respectively, while the head of the capitate bone and the superior surface of the hamate bone rotate in the cup-shaped cavity of the navicular and lunate bones. Flexion at this joint is freer than extension. A very trifling amount of rotation is also permitted, the head of the capitate bone rotating round a vertical axis drawn through its own centre, while at the same time a slight gliding movement takes place in the lateral and medial portions of the joint.

Applied Anatomy.—The radiocarpal joint is rarely dislocated, its strength depending mainly upon the numerous strong tendons which surround the articulation. Its security is further provided for by the number of small bones of which the carpus is made up, and which are united by very strong ligaments. The slight movements which take place between the several bones serve to break the jars that result from falls or blows on the hand. Dislocation backwards, which is the more common, simulates to a considerable extent Colles's fracture of the radius, and is liable to be mistaken for it. The differential diagnosis can be easily made by observing the relative positions of the styloid processes of the radius and the ulna. In the natural condition when the arm hangs by the side, the styloid process of the radius is on a lower level, i.e. nearer the ground, than that of the ulna, and this relationship is not disturbed in dislocation. In Colles's fracture, the styloid process of the radius is on the same level as, or even on a higher level than, that of the ulna.

The radiocarpal joint is occasionally the seat of acute synovitis. When the joint cavity is distended with fluid, the swelling is greatest on the dorsal aspect of the wrist, showing a general fulness, with some bulging between the tendons. The inflammation is prone to extend to the intercarpal joints and to attack also the sheaths of the tendons in the neighbourhood. Chronic inflammation of the wrist is generally tuberculous, and often leads to similar disease in the mucous sheaths of adjacent tendons and the intercarpal joints, with resulting ankylosis.

* H. M. Johnston (*Journal of Anatomy and Physiology*, vol. xli.) maintains that in ulnar and radial flexion only slight lateral movement occurs at the radiocarpal joint, and that in complete flexion and extension of the hand there is a small degree of ulnar flexion at the radiocarpal joint.

VIII. CARPOMETACARPAL ARTICULATIONS

1. CARPOMETACARPAL ARTICULATION OF THE THUMB

This is a joint of reciprocal reception between the first metacarpal and greater multangular bones; it enjoys great freedom of movement on account of the configuration of its articular surfaces, which are saddle-shaped. The joint is surrounded by an **articular capsule** which is thick but loose, and passes from the circumference of the base of the metacarpal bone to the rough edge bounding the articular surface of the greater multangular bone; it is thickest laterally and dorsally. A synovial stratum lines the capsule and is quite distinct from that of the other carpometacarpal joints.

Movements.—In this articulation the movements permitted are flexion and extension in the plane of the palm of the hand, abduction and adduction in a plane at right angles to the palm, circumduction, and opposition. It is by the movement of opposition that the tip of the thumb is brought into contact with the volar surfaces of the slightly flexed fingers. This movement is effected through the medium of a small sloping facet on the anterior lip of the saddle-shaped articular surface of the greater multangular bone. The flexor muscles pull the corresponding part of the articular surface of the metacarpal bone on to this facet, and the movement of opposition is then carried out by the adductor muscles.

Flexion of this joint is produced by the *Flexores pollicis longus* and *brevis*, assisted by the *Opponens pollicis* and the *Adductor pollicis*. Extension is effected mainly by the *Abductor pollicis longus*, assisted by the *Extensores pollicis longus* and *brevis*. Adduction is carried out by the *Adductor pollicis*; abduction mainly by the *Abductores pollicis longus* and *brevis*, assisted by the extensor muscles.

2. ARTICULATIONS OF THE SECOND, THIRD, AND FOURTH METACARPAL BONES WITH THE CARPUS

The joints between the carpus and the second, third, fourth, and fifth metacarpal bones are arthrodial. The bones are united by articular capsules, strengthened by dorsal, volar, and interosseous ligaments.

The **dorsal ligaments**, the strongest and most distinct, connect the carpal and metacarpal bones on their dorsal surfaces. The second metacarpal bone receives two fasciculi, one each from the greater and lesser multangular bones; the third metacarpal receives two, one each from the lesser multangular and capitate bones; the fourth two, one each from the capitate and hamate bones; the fifth receives a single fasciculus from the hamate bone, and this is continuous with a similar ligament on the volar surface, forming an incomplete fibrous capsule.

The **volar ligaments** have a somewhat similar arrangement, with the exception of those of the third metacarpal, which are three in number: a lateral one from the greater multangular bone, situated superficially to the sheath of the tendon of the *Flexor carpi radialis*; an intermediate one from the capitate bone; and a medial one from the hamate bone.

The **interosseous ligaments** consist of short, thick fibres, and are limited to one part of the carpometacarpal articulation; they connect the contiguous inferior angles of the capitate and hamate bones with the adjacent surfaces of the third and fourth metacarpal bones.

The **synovial stratum** of the articular capsules is a continuation of that of the intercarpal joints. Occasionally, the joint between the hamate bone and the fourth and fifth metacarpal bones has a separate synovial stratum.

Movements.—The movements permitted in the carpometacarpal articulations of the fingers are limited to slight gliding of the articular surfaces upon each other, the extent of which varies in the different joints. The metacarpal bone of the little finger is the most movable, then that of the ring-finger; the metacarpal bones of the index and middle fingers are almost immovable.

IX. INTERMETACARPAL ARTICULATIONS

The bases of the second, third, fourth, and fifth metacarpal bones articulate with one another by small surfaces covered with cartilage, and are connected together by dorsal, volar, and interosseous ligaments.

The **dorsal** and **volar ligaments** pass transversely from one bone to another on the dorsal and volar surfaces. The **interosseous ligaments** connect their contiguous surfaces, just distal to their collateral articular facets.

The **synovial stratum** of these joints is continuous with that of the carpo-metacarpal articulations.

The **transverse metacarpal ligament** (fig. 482) is a narrow fibrous band, which runs across the volar surfaces of the heads of the second, third, fourth, and fifth metacarpal bones, connecting them together. It is blended with the accessory volar ligaments (glenoid ligaments) of the metacarpophalangeal articulations. Its volar surface is grooved where the flexor tendons pass over it; behind the ligament the tendons of the Interossei pass to their insertions.

X. METACARPOPHALANGEAL ARTICULATIONS (figs. 484, 485)

These articulations are of the condyloid kind, formed by the reception of the rounded heads of the metacarpal bones into shallow cavities on the proximal

FIG. 484.—Metacarpophalangeal articulation and articulations of digit. Volar aspect.

FIG. 485.—Metacarpophalangeal articulation and articulations of digit. Ulnar aspect.

ends of the first phalanges, with the exception of that of the thumb, which presents more of the characters of a ginglymoid joint. Each joint has an accessory volar and two collateral ligaments.

ARTICULATIONS OF THE LOWER EXTREMITY

The **accessory volar ligaments** (*glenoid ligaments* of Cruveilhier) are thick, dense, fibrocartilaginous structures, placed upon the volar surfaces of the joints in the intervals between the collateral ligaments, to which they are connected; they are loosely united to the metacarpal bones, but are very firmly attached to the bases of the first phalanges. Their volar surfaces are intimately blended with the transverse metacarpal ligament, and grooved for the flexor tendons, the sheaths surrounding which are connected to the sides of the grooves. Their deep surfaces form parts of the articular facets for the heads of the metacarpal bones.

The **collateral ligaments** are strong, rounded cords, placed on the sides of the joints; each is attached by one extremity to the posterior tubercle and adjacent depression on the side of the head of the metacarpal bone, and by the other to the contiguous extremity of the phalanx.

The dorsal surfaces of these joints are covered by the expansions of the extensor tendons, together with some loose areolar tissue which connects the deep surfaces of the tendons to the bones.

Movements.—The movements which occur in these joints are flexion, extension, adduction, abduction, and circumduction; the movements of abduction and adduction are very limited, and cannot be performed when the fingers are flexed.

XI. DIGITAL ARTICULATIONS

The interphalangeal articulations are hinge-joints; each has a volar and two collateral ligaments. The arrangement of these ligaments is similar to those in the metacarpophalangeal articulations. The extensor tendons supply the places of posterior ligaments.

Movements.—The only movements permitted in the interphalangeal joints are flexion and extension; these movements are more extensive between the first and second phalanges than between the second and third. The amount of flexion is very considerable, but extension is limited by the volar and collateral ligaments.

MUSCLES ACTING ON THE JOINTS OF THE DIGITS

Flexion of the metacarpophalangeal joints of the fingers is effected by the *Flexores digitorum sublimis* and *profundus*, *Lumbricales*, and *Interossei*, assisted in the case of the little finger by the *Flexor digiti quinti brevis*. Extension is produced by the *Extensor digitorum communis*, *Extensor indicis proprius*, and *Extensor digiti quinti proprius*.

Flexion of the interphalangeal joints of the fingers is accomplished by the *Flexor digitorum profundus* acting on the proximal and distal joints and by the *Flexor digitorum sublimis* acting on the proximal joints. Extension is effected mainly by the *Lumbricales* and *Interossei*, the long extensors having little or no action upon these joints.

Flexion of the metacarpophalangeal joint of the thumb is effected by the *Flexores pollicis longus* and *brevis*; extension by the *Extensores pollicis longus* and *brevis*. Flexion of the interphalangeal joint is accomplished by the *Flexor pollicis longus*, and extension by the *Extensor pollicis longus*.

ARTICULATIONS OF THE LOWER EXTREMITY

The articulations of the lower extremity comprise the following:

- | | |
|----------------------|-------------------------|
| I. Sacro-iliac. | VI. Ankle. |
| II. Pubic symphysis. | VII. Intertarsal. |
| III. Hip. | VIII. Tarsometatarsal. |
| IV. Knee. | IX. Intermetatarsal. |
| V. Tibiofibular. | X. Metatarsophalangeal. |
| XI. Digital. | |

I. SACRO-ILIAIC ARTICULATION

The sacro-iliac articulation is an amphiarthrodial joint, formed between the auricular surfaces of the sacrum and ilium. The articular surface of each bone is covered with a plate of cartilage which is thicker on the sacrum than on the ilium. These plates are in close contact with each other, and to a certain extent are united by irregular patches of softer fibrocartilage, and at their upper and posterior part by fine interosseous fibres. In a considerable portion

FIG. 486. Articulations of pelvis. Anterosuperior view.

of their extent, especially in advanced life, they are separated by a space containing a synovia-like fluid, and hence part of the joint presents the characteristics of a diarthrosis. The ligaments of the joint are :

Anterior sacro-iliac. Posterior sacro-iliac.
Interosseous sacro-iliac.

The **anterior sacro-iliac ligament** (fig. 486) consists of numerous thin bands, which connect the anterior surface of the lateral part of the sacrum to the margin of the auricular surface of the ilium and to the pre-auricular sulcus.

The **posterior sacro-iliac ligament** (fig. 487) is situated in a deep depression between the sacrum and ilium behind ; it is strong and forms the chief bond of union between the bones. Its upper part, the *short posterior sacro-iliac ligament*, is nearly horizontal in direction, and passes from the first and second transverse tubercles on the back of the sacrum to the iliac tuberosity above and behind the auricular surface. Its lower part, the *long posterior sacro-iliac ligament*, is oblique in direction ; it is attached above to the third transverse tubercle of the back of the sacrum, where it is blended with the upper and

medial part of the sacrotuberous ligament, below, to the posterior superior spine of the ilium.

The **interosseous sacro-iliac ligament** lies deep to the posterior sacro-iliac ligament, and consists of a series of short, strong fibres connecting the iliac and sacral tuberosities.

The ilium is connected to the fifth lumbar vertebra by the *iliolumbar ligament*, and the sacrum to the ischium by the *sacrotuberous* and *sacrospinous ligaments*.

FIG. 487.—Articulations of pelvis. Posterior view.

The **iliolumbar ligament** (fig. 486) is attached above to the lower and front part of the transverse process of the fifth lumbar vertebra, and occasionally has an additional, weak attachment to the transverse process of the fourth. It radiates as it passes lateralwards and is attached by two main bands to the pelvis. The lower band runs to the ala of the ilium and the base of the sacrum, blending with the anterior sacro-iliac ligament: the upper is attached to the crest of the ilium immediately in front of the sacro-iliac articulation and is continuous above with the lumbodorsal fascia.

The **sacrotuberous ligament** (great sacrospinous ligament) (fig. 487) is placed at the lower and posterior part of the pelvis. It is flat, and somewhat triangular in form; it is attached by its broad base to the posterior inferior spine of the ilium, to the third, fourth, and fifth transverse tubercles of the sacrum, and to the lower part of the lateral margin of that bone and the coccyx. Passing obliquely downwards, forwards, and lateralwards, it becomes narrow and thick, but at its insertion into the inner margin of the tuberosity of the ischium it increases in breadth, and is prolonged forwards along the inner margin of the ramus as the *falciform process*, the free concave edge of which gives attachment

to the fascia of the Obturator internus. The lower border of the ligament is directly continuous with the tendon of origin of the long head of the Biceps femoris.

The **sacrospinous ligament** (small sacrosciatic ligament) (fig. 486) is thin, and triangular in form; it is attached by its apex to the spine of the ischium, and, medially, by its broad base, to the lateral margins of the sacrum and coccyx, in front of the sacrotuberous ligament, with which its fibres are intermingled. It is in relation in front with the Coccygeus muscle, to which it is closely connected, and of which it may represent a degenerated part.

These two ligaments convert the sciatic notches into foramina. The *greater sciatic foramen* is bounded, in front and above, by the greater sciatic notch: behind, by the sacrotuberous ligament; and below, by the sacrospinous ligament and the spine of the ischium. It is partially filled up, in the recent state, by the Piriformis muscle which emerges from the pelvis through it. Above this muscle, the superior gluteal vessels and nerve pass out of the pelvis; and below it, the inferior gluteal vessels and nerve, the internal pudendal vessels and nerve, the sciatic and posterior femoral cutaneous nerves, and the nerves to the Obturator internus and Quadratus femoris make their exit from the pelvis. The *lesser sciatic foramen* is bounded, in front, by the superior ramus of the ischium; above, by the spine of the ischium and sacrospinous ligament: behind, by the sacrotuberous ligament. It transmits the tendon of the Obturator internus, its nerve, and the internal pudendal vessels and nerve.

II. PUBIC SYMPHYSIS

The ligaments of the pubic symphysis are :

Superior pubic.

Arcuate pubic.

Interpubic fibrocartilaginous lamina.

The **superior pubic ligament** connects together the two pubic bones superiorly, and extends as far as the pubic tubercles.

FIG. 488.-- Pubic symphysis exposed by a coronal section.

The **arcuate pubic ligament** (inferior or subpubic ligament) is a thick, triangular arch of fibres, connecting the two pubic bones below, and forming the upper boundary of the pubic arch. Above, it is blended with the interpubic

fibrocartilaginous lamina; laterally, it is attached to the inferior rami of the pubic bones; below, it is free, and is separated from the fascia of the urogenital diaphragm by an opening through which, in the male, the deep dorsal vein of the penis enters the pelvis.

The **interpubic fibrocartilaginous lamina** connects the opposed surfaces of the pubic bones. Each of these surfaces is covered by a thin layer of hyaline cartilage firmly joined to the bone by a series of nipple-like processes which accurately fit into corresponding depressions on the osseous surfaces. These opposed cartilaginous surfaces are connected together by a lamina of fibrocartilage which varies in thickness in different subjects. It often contains a cavity in its interior, probably formed by the softening and absorption of the fibrocartilage, since it rarely appears before the tenth year of life and is not lined by a synovial stratum. This cavity is usually limited to the upper and back part of the joint; it occasionally reaches the front, and may extend the entire length of the cartilage. It may be easily demonstrated when present by making a coronal section of the symphysis pubis near its posterior surface (fig. 488). In front, the lamina is strengthened by several superimposed layers of fibres, which pass obliquely from one bone to the other, decussating and forming an interlacement with the fibres of the aponeuroses of the *Obliqui externi* and the medial tendons of origin of the *Recti abdominis*.

MECHANISM OF THE PELVIS

The pelvic girdle supports and protects the contained viscera and affords surfaces for the attachments of the muscles of the trunk and lower limb. Its most important mechanical function, however, is to transmit the weight of the trunk and upper limbs to the lower extremities.

It may be divided into two arches by a vertical plane passing through the acetabular cavities; the posterior of these arches is the one chiefly concerned in the function of transmitting the weight. Its essential parts are the upper three sacral vertebrae and two strong pillars of bone running from the sacro-iliac articulations

FIG. 489.—Coronal section of anterior sacral segment.

to the acetabular cavities. For the reception and diffusion of the weight each acetabular cavity is strengthened by two additional bars running towards the os pubis and the ischium. In order to lessen concussion in rapid changes of distribution of the weight, joints (sacro-iliac articulations) are interposed between the sacrum and the iliac bones; an accessory joint (symphysis pubis) exists in the middle of the anterior arch. The sacrum forms the summit of the posterior arch; the weight transmitted falls on it at the lumbosacral articulation and, theoretically, has a component in each of two directions. One component of the force is expended in driving the sacrum downwards and backwards between the iliac bones, while the other thrusts the upper end of the sacrum downwards and forwards towards the pelvic cavity.

The movements of the sacrum are regulated by its form. Viewed as a whole, it presents the shape of a wedge with its base upwards and forwards. The first component of the force is therefore acting against the resistance of the wedge, and its tendency to separate the iliac bones is resisted by the sacro-iliac and iliolumbar ligaments and by the ligaments of the symphysis pubis.

If a series of coronal sections of the sacro-iliac joints be made, it will be found possible to divide the articular portion of the sacrum into three segments: anterior, middle, and posterior. In the *anterior segment* (fig. 489), which involves the first sacral vertebra, the articular surfaces show slight sinuositics and are almost parallel

FIG. 490.—Coronal section of middle sacral segment.

to one another; the distance between their dorsal margins is, however, slightly greater than that between their ventral margins. This segment therefore presents a slightly wedge-shape with the truncated apex downwards. The *middle segment* (fig. 490) is a narrow bar across the centres of the articulations. Its dorsal width is distinctly greater than its ventral, so that the segment is more definitely wedge-shaped, the truncated apex being again directed downwards. Each sacral articular surface presents in the centre a marked concavity from above downwards, and into this a corresponding convexity of the iliac articular surface fits, forming an interlocking mechanism. In the *posterior segment* (fig. 491) the ventral width is greater than the dorsal, so that the wedge-form is the reverse of those of the other segments.

FIG. 491.—Coronal section of posterior sacral segment.

--i.e. the truncated apex is directed upwards. The articular surfaces are only slightly concave.

Dislocation downwards and forwards of the sacrum by the second component of the force applied to it is prevented therefore by the middle segment, which interposes the resistance of its wedge shape and that of the interlocking mechanism on its surfaces; a rotatory movement, however, is produced by which the anterior segment is tilted downwards and the posterior

upwards: the axis of this rotation passes through the dorsal part of the middle segment. The movement of the anterior segment is slightly limited by its wedge-form, but chiefly by the posterior and interosseous sacro-iliac ligaments; that of the posterior segment is checked to a slight extent by its wedge-form, but the chief limiting factors are the sacrotuberous and sacrospinous ligaments. In all these movements the effect of the sacro-iliac and iliolumbar ligaments and the ligaments of the symphysis pubis in resisting the separation of the iliac bones must be recognised.

During pregnancy the pelvic joints and ligaments are relaxed, and capable therefore of more extensive movements. When the foetus is being expelled the force is applied to the front of the sacrum. Upward dislocation is prevented by

the interlocking mechanism of the middle segment. As the foetal head passes the anterior segment the latter is carried upwards, enlarging the anteroposterior diameter of the pelvic inlet; when the head reaches the posterior segment this also is pressed upwards against the resistance of its wedge, the movement only being possible by the laxity of the joints and the stretching of the sacrotuberous and sacrospinous ligaments.

III. COXAL ARTICULATION OR HIP-JOINT

The hip-joint is an enarthrodial, or ball-and-socket articulation, formed by the reception of the head of the femur into the cup-shaped cavity of the acetabulum. The articular cartilage on the head of the femur, thicker at the centre than at the circumference, covers the entire surface with the exception

FIG. 492.—Articular capsule of hip-joint (distended). Posterior aspect.

of the fovea capitis femoris, to which the ligamentum teres is attached; that on the acetabulum forms an incomplete ring, the lunate surface. Within the lunate surface there is a circular depression devoid of cartilage, occupied in the recent state by a mass of fat covered by the synovial stratum of the articular capsule. The ligaments of the joint are:

The articular capsule.
Iliofemoral.
Ischiocapsular.

Pubocapsular.
Ligamentum teres femoris.
The glenoidal labrum.

Transverse acetabular.

The **articular capsule** (fig. 492) is strong and dense. Above, it is attached to the margin of the acetabulum, 5 or 6 mm. beyond the glenoidal labrum behind; in front, it is attached to the outer margin of the labrum, and, opposite the acetabular notch, it is connected to the transverse acetabular ligament

and the edge of the obturator foramen. It surrounds the neck of the femur, and is attached, in front, to the intertrochanteric line; above, to the base of the neck; behind, to the neck, about 1.25 cm. above the intertrochanteric crest; below, to the lower part of the neck close to the lesser trochanter. From its femoral attachment some of the fibres are reflected upwards along the neck as longitudinal bands, termed *retinacula*. The capsule is much thicker at the upper and fore part of the joint, where the greatest amount of resistance is required; behind and below, it is thin and loose. It consists of two sets of fibres, circular and longitudinal. The circular fibres (*zona orbicularis*) are most abundant at the lower and back part of the capsule (fig. 492), and form a sling

FIG. 493.—Right hip-joint from the front.

or collar around the neck of the femur. Anteriorly, they blend with the deep surface of the iliofemoral ligament, and gain an attachment to the anterior inferior iliac spine. The longitudinal fibres are greatest in amount at the upper and front part of the capsule, where they are reinforced by the *iliofemoral ligament*. The articular capsule is also strengthened by the *pubocapsular* and the *ischiocapsular ligaments*. The external surface of the capsule is rough, covered by numerous muscles, and separated in front from the Psoas major and Iliacus by a bursa, which not infrequently communicates by a circular aperture with the cavity of the joint.

The *synovial stratum* is very extensive. Commencing at the margin of the cartilaginous surface of the head of the femur, it covers the portion of the neck which is contained within the joint; from the neck it is reflected on the internal surface of the fibrous stratum of the capsule, covers both surfaces of the glenoidal labrum, ensheathes the ligamentum teres as far as the head of the femur, and covers the mass of fat contained in the bottom of the acetabulum. The joint cavity sometimes communicates, through a hole in the capsule between the vertical band of the iliofemoral ligament and the pubo-

capsular ligament, with a bursa situated on the deep surfaces of the Psoas major and Iliacus.

The iliofemoral ligament (fig. 493), triangular in shape and of great strength, lies in front of the joint and is intimately connected with the capsule. Its apex is attached to the lower part of the anterior inferior iliac spine, its base to the intertrochanteric line of the femur. The medial and lateral parts of the ligament are strong bands, while the central part is relatively thin and weak; the medial band is vertical in direction and is fixed to the lower part of the intertrochanteric line; the lateral band is oblique and is attached to the upper part of the same line. The iliofemoral ligament is frequently called the Y-shaped ligament of Bigelow, and its lateral band the *iliotrochanteric ligament*.

FIG. 494.—Right hip-joint from behind.

The pubocapsular ligament (fig. 493) is triangular in form with its base at the hip-bone, where it is attached to the iliopectineal eminence, the superior ramus of the os pubis, the obturator crest and obturator membrane; below, it blends with the capsule and with the deep surface of the medial band of the iliofemoral ligament.

The ischiofemoral ligament (fig. 494) has a somewhat spiral disposition on the back of the joint. From its attachment to the ischium below and behind the acetabulum, it is directed upwards and lateralwards over the back of the neck of the femur. Some of its fibres are continuous with those of the zona orbicularis, others are implanted on to the greater trochanter.

The ligamentum teres femoris (fig. 495) is a triangular, somewhat flattened band implanted by its apex on the anterosuperior part of the fovea capitis femoris; its base is attached by two bands, one into either side of the acetabular notch, and between these bony attachments it blends with the transverse ligament. It is ensheathed by the synovial stratum, and varies greatly in strength in different subjects; occasionally only the synovial stratum exists, and in rare cases even this is absent. The ligament is made tense when the thigh is semiflexed and the limb then adducted or rotated outwards; it is relaxed when the limb is abducted.

The **glenoidal labrum** (cotyloid ligament) is a fibrocartilaginous rim attached to the margin of the acetabulum, the cavity of which it deepens; at the same time it protects the edge of the bone, and fills up the inequalities of its surface. It bridges over the notch as the *transverse acetabular ligament*, and thus forms a complete circle, which closely surrounds the head of the femur and assists in holding it in its place. It is triangular on section, its base being attached to the margin of the acetabulum, while its opposite edge is free and sharp. Its surfaces are invested by the synovial stratum; the internal surface is inclined inwards so as to narrow the acetabulum, and embrace the cartilaginous surface of the head of the femur. It is much thicker above and behind than below and in front.

FIG. 495.—Left hip-joint, opened by removing the floor of the acetabulum from within the pelvis.

The **transverse acetabular ligament** is in reality a portion of the glenoidal labrum, though differing from it in having no cartilage-cells among its fibres. It consists of strong, flattened fibres, which cross the acetabular notch, and convert it into a foramen through which the nutrient vessels enter the joint.

The *muscles* in relation with the joint are, in front, the Psoas major and Iliacus, separated from the capsule by a bursa; above, the reflected head of the Rectus femoris and the insertion of Glutæus minimus, the latter being closely adherent to the capsule; medially, the Obturator externus and Pectineus; behind the Piriformis, Gemellus superior, tendon of Obturator internus, Gemellus inferior, tendon of Obturator externus, and Quadratus femoris (fig. 496).

The *arteries* supplying the joint are derived from the obturator, medial femoral circumflex, and superior and inferior glutæal arteries.

The *nerves* are articular branches from the sacral plexus, sciatic, obturator, accessory obturator, and a filament from the branch of the femoral supplying the Rectus femoris.

Movements. --The movements of the hip-joint are very extensive, and consist of flexion, extension, adduction, abduction, circumduction, and rotation.

The length of the neck of the femur and its inclination to the body of the bone have the effect of converting the angular movements of flexion, extension, adduction, and abduction partially into rotatory movements in the joint. Thus when the thigh is flexed or extended, the head of the femur, on account of the *medial* inclination of the neck, rotates within the acetabulum with only a slight amount of gliding to and fro. The *forward* slope of the neck similarly affects the movements of adduction and abduction. Conversely rotation of the thigh, which is permitted by the *upward* inclination of the neck, is not a simple rotation of the head of the femur in the acetabulum, but is accompanied by a certain amount of gliding.

FIG. 496.--Structures surrounding right hip-joint.

The hip-joint presents a very striking contrast to the shoulder-joint in the much more complete mechanical arrangements for its security and for the limitation of its movements. In the shoulder, as has been seen, the head of the humerus is not adapted at all in size to the glenoid cavity, and is hardly restrained in any of its ordinary movements by the capsule. In the hip-joint, on the contrary, the head of the femur is closely fitted to the acetabulum for an area extending over nearly half a sphere, and at the margin of the bony cup it is still more closely embraced by the glenoidal labrum, so that the head of the femur is held in its place by that ligament even when the fibres of the capsule have been quite divided. The iliofemoral ligament is the strongest of all the ligaments in the body, and is put on the stretch by any attempt to extend the femur beyond a straight line with the trunk. That is to say, this ligament is the chief agent in maintaining the erect position without muscular fatigue; for a vertical line passing through the centre of gravity of the trunk falls behind the centres of rotation in the hip-joints, and therefore the pelvis tends to fall backwards, but is prevented by the tension of the iliofemoral ligaments. The security of the joint may be provided for also by the two bones being directly united through the ligamentum teres; but it is doubtful whether this ligament has much influence upon the mechanism of the joint. When the knee is flexed,

flexion of the hip-joint is arrested by the soft parts of the thigh and abdomen being brought into contact, and when the knee is extended, by the action of the hamstring muscles; extension is checked by the tension of the iliofemoral ligament; adduction by the thighs coming into contact; adduction with flexion by the lateral band of the iliofemoral ligament and the lateral part of the capsule; abduction by the medial band of the iliofemoral ligament and the pubocapsular ligament; rotation outwards by the lateral band of the iliofemoral ligament; and rotation inwards by the ischio-capsular ligament and the hinder part of the capsule. The muscles which *flex* the femur on the pelvis are the Psoas major, Iliacus, Rectus femoris, Sartorius, Pectineus, Adductores longus and brevis, and the anterior fibres of the Glutæi medius and minimus. *Extension* is mainly performed by the Glutæus maximus, assisted by the hamstring muscles and the ischial head of the Adductor magnus. The thigh is *adducted* by the Adductores magnus, longus, and brevis, the Pectineus, the Gracilis, and lower part of the Glutæus maximus, and *abducted* by the Glutæi medius and minimus, and the upper part of the Glutæus maximus. The muscles which *rotate* the thigh *inwards* are the Glutæus minimus and the anterior fibres of the Glutæus medius, the Tensor fasciæ latæ and the Iliacus and Psoas major; while those which rotate it *outwards* are the posterior fibres of the Glutæus medius, the Piriformis, Obturatores externus and internus, Gemelli superior and inferior, Quadratus femoris, Glutæus maximus, the Adductores longus, brevis, and magnus, the Pectineus, and the Sartorius.

Applied Anatomy.—In dislocation of the hip, 'the head of the thigh-bone may rest at any point around its socket' (Bryant); but whatever position it ultimately assumes, the primary displacement is generally downwards and medialwards, the capsule giving way at its weakest—that is, its lower and medial—part. The situation subsequently assumed by the head of the bone is determined by the degree of flexion or extension, and of outward or inward rotation of the thigh at the moment of dislocation, influenced, no doubt, by the iliofemoral ligament, which is not easily ruptured. When, for instance, the head of the bone is forced backwards, this ligament forms a fixed axis, round which the head of the bone rotates, and is driven on to the dorsum of the ilium. The iliofemoral ligament also influences the position of the thigh in the various dislocations: in the dislocations backwards it is tense, and produces inversion of the limb; in the dislocation on to the os pubis, it is relaxed, and therefore allows the external rotator muscles to evert the thigh; while in dislocation into the obturator foramen it is tense, and produces flexion. The muscles inserted into the upper part of the femur, with the exception of the Obturator internus, have very little direct influence in determining the position of the head of the bone. Bigelow, however, has endeavoured to show that the Obturator internus is the principal agent in deciding whether, in the backward dislocations, the head of the bone shall be ultimately lodged on the dorsum of the ilium, or in or near the greater sciatic notch; in both dislocations the head passes, in the first instance, in the same direction. But, as Bigelow asserts, in the displacement on to the dorsum the head of the bone travels up behind the acetabulum, in front of the muscle; while in the dislocation into the greater sciatic notch the head passes behind the muscle, and is prevented from reaching the dorsum, in consequence of the tendon of the muscle arching over the neck of the bone, and it therefore remains in the neighbourhood of the notch. Bigelow distinguishes these two forms of dislocation by describing them as dislocations backwards, 'above and below' the Obturator internus.

The iliofemoral ligament is rarely torn in dislocations of the hip, and this fact is taken advantage of by the surgeon in reducing these dislocations by manipulation. It is made to act as the fulcrum to a lever, of which the long arm is the body of the femur, and the short arm the neck of the bone (fig. 497).

The hip-joint is rarely the seat of acute synovitis from injury, on account of its deep position and its thick covering of soft parts. Acute inflammation may, and does, frequently occur as the result of bacterial infections, as in rheumatism, pyæmia, etc. When, in these cases, effusion takes place, and the joint is distended with fluid, the swelling is not very easy to detect on account of the thickness of the capsule and the depth of the articulation. It is principally to be found on the front of the joint, just medial to the iliofemoral ligament; or behind, at the lower and back part. In these two places the capsule is thinner than elsewhere. Disease of the hip-joint is much oftener of a chronic character, and is usually of tuberculous origin. It begins usually in the bone, and, in most cases, in the growing, highly vascular tissue in the neighbourhood of the epiphysal cartilage of the femoral head. In this respect it differs very materially from tuberculous arthritis of the knee, where the disease usually commences in the synovial stratum.

In chronic hip-disease the affected limb assumes an altered position, the cause of which it is important to understand. In the early stage of a typical case, the limb is flexed, abducted, and rotated outwards. In this position all the ligaments of the joint are relaxed: the front of the capsule by flexion; the lateral band of the iliofemoral ligament by abduction; and the medial band of this ligament and the back of the capsule

by rotation outwards. It is, therefore, the position of greatest ease. The condition is not quite obvious at first, upon examining a patient. If the patient be laid in the supine position, the affected limb will be found to be extended and parallel with the other. But it will be seen that the pelvis is tilted downwards on the diseased side and the limb apparently longer than its fellow, and that the lumbar portion of the vertebral column is arched forwards (lordosis). The condition is thus explained: a limb which is flexed and abducted is obviously useless for progression, and in order to overcome the difficulty the patient depresses the affected side of his pelvis, thus producing parallelism of his limbs, and at the same time rotates his pelvis on its transverse horizontal axis, so as to direct the limb downwards, instead of forwards. In the later stages of the disease the limb becomes flexed and adducted and inverted. This position probably depends upon muscular action, at all events as regards the adduction. The Adductor muscles are supplied by the obturator nerve, which also largely supplies the joint. These muscles are therefore thrown into reflex spasm by the irritation of the peripheral terminations of this nerve in the inflamed articulation.

Osteo-arthritis is common in the hip-joint, and more so in the male than in the female, in whom the knee-joint is more frequently affected. It is a disease of middle age or advanced life. When much deformity is associated with chronic osteo-arthritis the condition is spoken of as *arthritis deformans of the hip*, or *morbus coxæ senilis*. The head of the femur is worn away, and after it often the neck too, until a new irregular articular surface is produced, around which a new formation of bone occurs, and also about the edges of the acetabulum, which is widened and eroded by a similar chronic process. Pain in the joint, shortening of the limb, and great limitation of movement result, with much creaking and grating when the joint is moved.

Congenital dislocation is more commonly met with in the hip-joint than in any other articulation. The displacement usually takes place on to the dorsum ilii. It gives rise to extreme lordosis, and a waddling gait is noticed as soon as the child commences to walk.

Excision of the hip may be required for disease or for injury, especially gunshot. It may be performed either by an anterior or a posterior incision. The former entails less interference with important structures, especially muscles, than the latter, but permits of less efficient drainage. In the operation from the front an incision is made 8 to 10 cm. in length, starting immediately below and lateral to the anterior superior iliac spine, downwards between the Sartorius and Tensor fasciæ latæ. The interspace between the Gluteus minimus and Rectus femoris is then opened up, exposing the upper part of the capsule, which being incised discloses the neck of the bone. This can now be divided, and the head of the bone extracted. The posterior method consists in making an incision 8 to 10 cm. long, commencing midway between the top of the greater trochanter and the iliac crest, and extending down the posterior border of the trochanter. The muscles are detached from the greater trochanter, and the capsule opened freely. The head and neck are freed from the soft parts and as much affected bone removed as is thought necessary.

FIG. 497.—Hip-joint, showing the iliofemoral ligament. (After Bigelow.)

IV. KNEE-JOINT

The knee-joint was formerly described as a ginglymus or hinge-joint, but is really of a much more complicated character. It must be regarded as consisting of three articulations in one: two condyloid joints, one between either condyle of the femur and the corresponding meniscus and condyle of the tibia; and a third between the patella and the femur, partly arthrodial, but not completely so, since the articular surfaces are not mutually adapted to each other, so that the movement is not a simple gliding one. This view of the construction of the knee-joint receives confirmation from a study of the articulation in some of the lower mammals, where, corresponding to these three subdivisions,

three synovial cavities are sometimes found, either entirely distinct or or connected together by small communications. This view is further rendered probable by the existence in the middle of the joint of the two cruciate ligaments, which may be regarded as the collateral ligaments of the medial and lateral joints. The existence of the patellar fold of synovial membrane would

FIG. 498.—Articular capsule of right knee-joint (distended). Lateral aspect.

further indicate a tendency to separation of the synovial cavity into two minor sacs, one corresponding to the lateral and the other to the medial joint.

The ligaments of the joint are :

The articular capsule.	Anterior cruciate.
Ligamentum patellae.	Posterior cruciate.
Oblique popliteal.	Medial and lateral menisci.
Arcuate popliteal.	Transverse.
Tibial collateral.	Coronary.
Fibular collateral	

The **articular capsule** (figs. 498, 499) consists of a fibrous stratum which is strengthened in almost its entire extent by bands inseparably connected with it; above and in front, beneath the tendon of the Quadriceps femoris, it is represented only by the synovial stratum. Its chief strengthening bands are derived from the fascia lata and from the tendons surrounding the joint. In front, expansions from the Vasti and from the fascia lata and its iliotibial tract fill in the intervals between the anterior and collateral ligaments, constituting the *medial and lateral patellar retinacula*. Behind, the capsule consists of vertical fibres which arise from the condyles of the femur and tibia and from

the sides of the inter-condyloid fossa of the femur; the posterior part of the capsule is therefore situated on the sides, and in front, of the cruciate ligaments, which are thus excluded from the joint-cavity. Behind the cruciate ligaments is the oblique popliteal ligament which is augmented by fibres derived from the tendon of the Semimembranosus. Laterally, a prolongation from the iliotibial tract fills the interval between the oblique popliteal and the fibular collateral ligaments, and partly covers the latter. Medially, expansions from the Sartorius and Semimembranosus pass upwards to the tibial collateral ligament and strengthen the capsule.

FIG. 499.—Articular capsule of right knee-joint (distended). Posterior aspect.

The **synovial stratum** of the knee-joint is the largest and most extensive in the body. Commencing at the upper border of the patella, it forms a large pouch beneath the Quadriceps femoris on the lower part of the front of the femur (figs. 498, 505), and usually communicates with a bursa interposed between the tendon and the front of the femur. The pouch between the Quadriceps and front of the femur is supported, during the movements of the knee, by a small muscle, the *Articularis genus*, which is inserted into it. On either side of the patella, the synovial stratum extends beneath the aponeuroses of the Vasti, and more especially beneath that of the Vastus medialis. Below the patella it is separated from the ligamentum patellæ by a considerable quantity of fat, known as the *infrapatellar pad*. From the medial and lateral borders of the articular surface of the patella, reduplications of the synovial stratum project into the interior of the joint. These form two fringe-like folds termed the *alar folds*; below, these folds converge and are continued as a single band, the *patellar fold* (*ligamentum mucosum*), to the front of the intercondyloid fossa of the femur. On either side of the joint, the synovial stratum passes downwards from the femur, lining the fibrous stratum of the capsule as far as its attachment to the menisci; it may then be traced over the upper

surfaces of these to their free borders, and thence along their under surfaces to the tibia. At the back part of the lateral meniscus it forms a cul-de-sac between the groove on its surface and the tendon of the Popliteus; it is reflected across the front of the cruciate ligaments, which are therefore situated outside the synovial cavity.

The *ligamentum patellæ* (fig. 500) is the central portion of the common tendon of the Quadriceps femoris, which is continued from the patella to the tuberosity of the tibia. It is a strong, flat, ligamentous band, about 8 cm. in length, attached, above, to the apex and adjoining margins and to the rough depression on the posterior surface of the patella; and below, to the tuberosity

FIG. 500.—Right knee-joint.
Anteromedial view.

of the tibia; its superficial fibres are continuous over the front of the patella with those of the tendon of the Quadriceps femoris. The medial and lateral portions of the tendon of the Quadriceps pass down on either side of the patella, to be inserted into the upper extremity of the tibia on either side of the tuberosity; these portions merge into the capsule, as stated above, forming the medial and lateral patellar retinacula. The posterior surface of the ligamentum patellæ is separated from the synovial stratum of the articular capsule by a large infrapatellar pad of fat, and from the tibia by a bursa.

The oblique popliteal ligament (posterior ligament) (fig. 501) is a broad, flat, fibrous band, formed of fasciculi separated from one another by apertures for the passage of vessels and nerves. It is attached above to the upper margin of the intercondyloid fossa and lateral condyle of the femur, and below it shades off into the capsule. Superficially there is a strong fasciculus derived from the tendon of the Semimembranosus; it passes from the posterior part of the medial condyle of the tibia obliquely upwards and lateralwards to the posterior part of the lateral condyle of the femur. The oblique popliteal ligament forms part of the floor of the popliteal fossa, and the popliteal artery rests upon it.

The arcuate popliteal ligament (fig. 501) is an arched bundle of fibres

which varies somewhat in strength and appearance. It is attached to the lateral condyle of the femur and passes downwards to fuse with the capsule below the oblique popliteal ligament. Two bands, an anterior and a posterior, converge from the upper and lower extremities of the arcuate popliteal ligament; they unite below to form the *retinaculum* of the ligament, which is fixed to the apex of the head of the fibula. The anterior band of this retinaculum is sometimes described as the *short fibular collateral ligament*.

The tibial collateral ligament (internal lateral ligament) (figs. 500, 501) is a broad, flat band, situated nearer to the back than to the front of the joint. It is attached, above, to the medial epicondyle of the femur immediately below the adductor tubercle; below, to the medial condyle and medial surface of the body of the tibia. The fibres of the posterior part of the ligament are short and incline backwards as they descend; they are inserted into the tibia above the groove for the Semimembranosus. The anterior part of the ligament, about 10 cm. long, inclines forwards as it descends; it is inserted into the medial surface of the body of the tibia about 2.5 cm. below the level of the condyle. It is crossed, at its lower part, by the tendons of the Sartorius Gracilis, and Semitendinosus, a bursa being interposed. Its deep surface covers

the inferior medial genicular vessels and nerve and the anterior portion of the tendon of the Semimembranosus, with which it is connected by a few fibres ; it is intimately adherent to the medial meniscus.

The **fibular collateral ligament** (external lateral ligament) (fig. 503) is a strong, rounded cord, attached, above, to the lateral epicondyle of the femur, immediately above the groove for the tendon of the Popliteus ; below, to the lateral side of the head of the fibula, in front of the styloid process. The greater part of its lateral surface is covered by the tendon of the Biceps femoris ; the tendon, however, divides at its insertion into two parts, which are separated

FIG. 501.—Right knee-joint
Posterior view.

FIG. 502.—Right knee-joint, dissected
from the front.

by the ligament. Deep to the ligament are the tendon of the Popliteus, and the inferior lateral genicular vessels and nerve. The ligament has no attachment to the lateral meniscus.

The **cruciate ligaments** are of considerable strength, and are situated in the middle of the joint, nearer to its posterior than to its anterior surface. They are called *cruciate* because they cross each other somewhat like the lines of the letter X ; and have received the names *anterior* and *posterior*, from the position of their attachments to the tibia.

The **anterior cruciate ligament** (fig. 502) is attached to the depression in front of the intercondyloid eminence of the tibia, being blended with the anterior extremity of the lateral meniscus ; it passes upwards, backwards, and lateralwards, and is fixed into the medial and back part of the lateral condyle of the femur.

The **posterior cruciate ligament** (fig. 503) is stronger, but shorter and less oblique in its direction, than the anterior. It is attached to the posterior intercondyloid fossa of the tibia, and to the posterior extremity of the lateral meniscus ; it passes upwards, forwards, and medialwards, to be fixed into the lateral and front part of the medial condyle of the femur.

The **menisci** (semilunar fibrocartilages) (fig. 504) are two crescentic lamellæ, which serve to deepen the surfaces of the head of the tibia for articulation with the condyles of the femur. The peripheral border of each meniscus is thick, convex, and attached to the inside of the articular capsule; the opposite border is thin, concave, and free. The upper surfaces of the menisci are concave, and in contact with the condyles of the femur; their lower surfaces are flat, and rest upon the head of the tibia; both surfaces are smooth, and enveloped by the synovial stratum. Each meniscus covers approximately the peripheral two-thirds of the corresponding articular surface of the tibia.

The **medial meniscus** is nearly semicircular in form, a little elongated from before backwards, and broader behind than in front; its anterior end is attached to the anterior intercondyloid fossa of the tibia, in front of the anterior cruciate

FIG. 503.—Left knee-joint, dissected from behind.

ligament, some of its fibres being continued, as the transverse ligament, to the anterior margin of the lateral meniscus; its posterior end is fixed to the posterior intercondyloid fossa of the tibia, between the attachments of the lateral meniscus and the posterior cruciate ligament.

The **lateral meniscus** is nearly circular and covers a larger portion of the articular surface than the medial meniscus. It is grooved posteriorly for the tendon of the Popliteus, which separates it from the fibular collateral ligament. Its anterior end is attached in front of the intercondyloid eminence of the tibia, behind and lateral to the anterior cruciate ligament, with which it blends; the posterior end is attached behind the intercondyloid eminence of the tibia and in front of the posterior end of the medial meniscus. The anterior attachment of the lateral meniscus is twisted on itself so that its free margin looks backwards and upwards, its anterior end resting on a sloping shelf of bone on the front of the lateral process of the intercondyloid eminence. Close to its posterior attachment it sends off a strong fasciculus, the *ligament of Wrisberg* (figs. 503, 504), which passes upwards and medialwards, to be inserted into the medial condyle of the femur, immediately behind the attachment of the posterior

cruciate ligament. Occasionally a small fasciculus passes forwards to be inserted into the lateral part of the anterior cruciate ligament. The lateral meniscus gives off from its anterior convex margin a fasciculus which forms the transverse ligament.

The **transverse ligament** (fig. 504) connects the anterior convex margin of the lateral meniscus to the anterior end of the medial meniscus; its thickness varies considerably in different subjects, and it is sometimes absent.

The **coronary ligaments** are merely portions of the capsule, connecting the periphery of either meniscus with the margin of the head of the tibia.

Bursæ.—The bursæ near the knee-joint are the following:

In front there are four bursæ: a large one is interposed between the lower part of the patella and the skin, a small one between the upper part of the tibia and the ligamentum patellæ, a third between the lower part of the tuberosity of the tibia and the skin, and a fourth between the anterior surface of the lower part of the femur and the deep surface of the Quadriceps femoris which usually

FIG. 504.—Head of right tibia seen from above, showing menisci and attachments of ligaments.

communicates with the knee-joint (fig. 505). Laterally there are four bursæ: (1) one (which sometimes communicates with the joint) between the lateral head of the Gastrocnemius and the capsule; (2) one between the fibular collateral ligament and the tendon of the Biceps femoris; (3) one between the fibular collateral ligament and the tendon of the Popliteus (this is sometimes only an expansion from the next bursa); (4) one between the tendon of the Popliteus and the lateral condyle of the femur, usually an extension from the synovial stratum of the joint. Medially, there are five bursæ: (1) one between the medial head of the Gastrocnemius and the capsule: this sends a prolongation between the tendon of the medial head of the Gastrocnemius and the tendon of the Semimembranosus and often communicates with the joint; (2) one superficial to the tibial collateral ligament, between it and the tendons of the Sartorius, Gracilis, and Semitendinosus; (3) one deep to the tibial collateral ligament, between it and the tendon of the Semimembranosus (this is sometimes only an expansion from the next bursa); (4) one between the tendon of the Semimembranosus and the head of the tibia; (5) occasionally there is a bursa between the tendons of the Semimembranosus and Semitendinosus.

Structures around the joint.—In front, and at the sides, is the Quadriceps femoris; laterally, the tendons of the Biceps femoris and Popliteus and the common peroneal nerve; medially, the Sartorius, Gracilis, Semitendinosus, and Semimembranosus; behind, the popliteal vessels, and the tibial nerve, Popliteus, Plantaris, and medial and lateral heads of the Gastrocnemius, some lymph-glands, and fat.

The *arteries* supplying the joint are the highest genicular (*anastomotica magna*), a branch of the femoral, the genicular branches of the popliteal, the recurrent branches of the anterior tibial, and the descending branch from the lateral femoral circumflex of the *arteria profunda femoris*.

The *nerves* are derived from the obturator, femoral, tibial, and common peroneal.

Movements.—The movements which take place at the knee-joint are flexion and extension, and, in certain positions of the joint, internal and external rotation. The movements of flexion and extension at this joint differ from those in a typical

FIG. 505.—Sagittal section of right knee-joint.

hinge-joint, such as the elbow, in that (a) the axis round which motion takes place is not a fixed one, but shifts forwards during extension and backwards during flexion; (b) the commencement of flexion and the end of extension are accompanied by rotatory movements associated with the fixation of the limb in a position of great stability. The movement from full flexion to full extension may therefore be described in three phases:

1. In the fully flexed condition the posterior parts of the femoral condyles rest on the corresponding portions of the meniscotibial surfaces, and in this position a slight amount of simple rolling movement is allowed.

2. During the passage of the limb from the flexed to the extended position a gliding movement is superposed on the rolling, so that the axis, which at the com-

ment is represented by a line through the medial and lateral condyles of the femur, gradually shifts forwards. In this part of the movement, the posterior two-thirds of the tibial articular surfaces of the two femoral condyles are involved, and as these have similar curvatures and are parallel to one another, they move forwards equally.

3. The lateral condyle of the femur is brought almost to rest by the tightening of the anterior cruciate ligament; it moves, however, slightly forwards and medialwards, pushing before it the anterior part of the lateral meniscus. The tibial surface on the medial condyle is prolonged farther forwards than that on the lateral, and this prolongation is directed lateralwards. When, therefore, the movement forwards of the condyles is checked by the anterior cruciate ligament, continued muscular action causes the medial condyle, dragging with it the meniscus, to travel backwards and medialwards, thus producing an internal rotation of the thigh on the leg. When the position of full extension is reached the lateral part of the groove on the lateral condyle is pressed against the anterior part of the corresponding meniscus, while the medial part of the groove rests on the articular margin in front of the lateral process of the tibial intercondyloid eminence. Into the groove on the medial condyle is fitted the anterior part of the medial meniscus, while the anterior cruciate ligament and the articular margin in front of the medial process of the tibial intercondyloid eminence are received into the fore part of the intercondyloid fossa of the femur. This third phase, by which all these parts are brought into accurate apposition, is known as the 'screwing home,' or locking movement of the joint.

The complete movement of flexion is the converse of that described above, and is therefore preceded by an external rotation of the femur which unlocks the extended joint.

The axes round which the movements of flexion and extension take place are not precisely at right angles to either bone; in flexion, the femur and tibia are in the same plane, but in extension the one bone forms an angle, opening lateralwards, with the other.

In addition to the rotatory movements associated with the completion of extension and the initiation of flexion, rotation inwards or outwards can be effected when the joint is partially flexed; these movements take place mainly between the tibia and the menisci, and are freest when the leg is bent at right angles with the thigh.

Movements of the patella.—The articular surface of the patella is indistinctly divided into seven facets—upper, middle, and lower horizontal pairs, and a medial perpendicular facet (fig. 506). When the knee is forcibly flexed, the medial perpendicular facet is in contact with the semilunar surface on the lateral part of the medial condyle; this semilunar surface is a prolongation backwards of the medial part of the patellar surface. As the leg is carried from the flexed to the extended position, first the highest pair, then the middle pair, and lastly the lowest pair of horizontal facets is successively brought into contact with the patellar surface of the femur. In the extended position, when the Quadriceps femoris is relaxed, the patella lies loosely on the front of the lower end of the femur.

During flexion, the ligamentum patellæ is stretched, and in extreme flexion the posterior cruciate ligament, the oblique popliteal and collateral ligaments and, to a slight extent, the anterior cruciate ligament, are relaxed. Flexion is checked during life by the contact of the leg with the thigh. When the knee joint is fully extended the oblique popliteal and collateral ligaments, the anterior cruciate ligament, and the posterior cruciate ligament, are rendered tense; in the act of extending the knee, the ligamentum patellæ is tightened by the Quadriceps femoris, but in full extension with the heel supported it is relaxed. Rotation inwards is checked by the anterior cruciate ligament; rotation outwards tends to uncross and relax the cruciate ligaments, but is checked by the tibial collateral ligament. The main function of the cruciate ligaments is to act as a direct bond between the tibia and femur and to prevent the former bone from being carried too far backwards or forwards. They also assist the collateral ligaments in resisting any bending of the

FIG. 506.—Posterior surface of the right patella, showing diagrammatically the areas of contact with the femur in different positions of the knee.

joint to either side. The menisci adapt the surfaces of the tibia to the shape of the femoral condyles to a certain extent, and so fill up the intervals which would otherwise be left in the varying positions of the joint, and permit of the two varieties of motion, flexion (and extension), and rotation, as explained above. The patella is a great defence to the front of the knee-joint, and distributes upon a large and tolerably even surface, during kneeling, the pressure which would otherwise fall upon the prominent ridges of the condyles; it also affords leverage to the Quadriceps femoris.

When standing erect in the attitude of 'attention,' the weight of the body falls in front of a line carried across the centres of the knee-joints, and therefore tends to produce over-extension of the articulation; this, however, is prevented by the tension of the anterior cruciate, oblique popliteal, and collateral ligaments.

Extension of the leg on the thigh is performed by the Quadriceps femoris; *flexion* by the Biceps femoris, Semitendinosus, and Semimembranosus, assisted by the Gracilis, Sartorius, Gastrocnemius, Popliteus, and Plantaris. *Rotation outwards* is effected by the Biceps femoris, and *rotation inwards* by the Popliteus, Semitendinosus, and, to a slight extent, by the Semimembranosus, the Sartorius, and the Gracilis. The Popliteus comes into action especially at the commencement of the movement of flexion of the knee; by its contraction, the leg is rotated inwards, or, if the tibia be fixed, the thigh is rotated outwards, and the knee-joint is unlocked.

Applied Anatomy.—From a consideration of the construction of the knee-joint, it would at first sight appear to be one of the least secure joints in the body. It is formed between the two longest bones, and therefore the amount of leverage which can be brought to bear upon it is considerable; the articular surfaces are but ill-adapted to each other, and the range of motion which it enjoys is great. All these circumstances tend to render the articulation insecure; nevertheless, on account of the powerful ligaments which bind the bones together, the joint is one of the strongest in the body, and dislocation from traumatism is a rare occurrence. When, on the other hand, the ligaments have been softened or destroyed by disease, partial displacement is liable to occur, and is frequently brought about by the action of the muscles.

One or other of the menisci may become displaced and nipped between the femur and tibia. The accident is produced by a twist of the leg when the knee is flexed, and is accompanied by a sudden pain and fixation of the knee in a flexed position. The meniscus may be displaced either towards the tibial intercondyloid eminence, so that the cartilage becomes lodged in the intercondyloid fossa, or to one side, so that the cartilage projects beyond the margin of the two articular surfaces. The medial meniscus is much more commonly affected than the lateral.

Acute synovitis, the result of traumatism, is of frequent occurrence in the knee, on account of the superficial position of the joint. When the cavity is distended with fluid, the swelling shows itself above and at the sides of the patella, reaching about 2.5 cm., occasionally 5 cm. or more, above the patellar surface of the femur, and extending a little higher under the Vastus medialis than under the Vastus lateralis. The lower level of the synovial stratum is just at the level of the head of the tibia. Chronic synovitis shows itself principally in the form of pulpy degeneration of the synovial stratum, the result of tuberculous infection. Syphilitic disease with gummatous infiltration of the synovial stratum may take place. The knee is one of the joints most commonly affected with osteo-arthritis, and is more frequently the seat of this disease in women than in men. The occurrence of the so-called loose cartilages is almost confined to the knee, though they are occasionally met with in other joints. Many of them occur in cases of osteo-arthritis in which calcareous or cartilaginous material is formed in one of the synovial fringes and constitutes the foreign body, and may or may not become detached, in the former case only meriting the usual term, 'loose' cartilage. In other cases they have their origin in the exudation of inflammatory lymph, and possibly, in some rare instances, a portion of the articular cartilages or one of the menisci becomes detached and constitutes the foreign body.

In inflammatory affections of the knee-joint, the position of greatest ease, and therefore the one which is always assumed, is that of slight flexion. In this position there is the most complete relaxation of ligamentous structures, and, therefore, the greatest diminution in the tension caused by the effusion. If this flexed position be maintained for any length of time, it becomes permanent from fibrous adhesions taking place, and the utility of the limb is materially impaired. Attention should therefore be paid by the surgeon to the position of the limb, and by carefully applied splints, with the leg in an extended position, this untoward result should be prevented. In cases of septic synovitis, incisions to evacuate the pus should be made vertically on either side of the patella, between it and the condyles of the femur.

Genu valgum, or knock-knee, is a common deformity of childhood. In this condition, as the patient stands, the medial condyles of the two femora are in contact, but the medial malleoli of the tibiae are more or less widely separated from each other. When,

however, the knees are flexed to a right angle, the two legs are practically parallel with each other. If the deformity be marked, an osteotomy of the femur is required to correct it.

Excision of the knee-joint is most frequently required for tuberculous disease of this articulation, but is also practised in cases of disorganisation of the knee from other causes and occasionally for injury, gunshot or otherwise. The operation is best performed by a horseshoe-shaped incision, starting from one femoral condyle, descending as low as the tuberosity of the tibia, and then carried upwards to the other femoral condyle. The bone ends having been cleared, and in those cases where the operation is performed for tuberculous disease all pulpy tissue having been carefully removed, the section of the femur is first made. This should never include, in children, more than, at the most, two-thirds of the articular surface, otherwise the epiphysal cartilage will be involved, with disastrous results as regards the growth of the limb. Afterwards a thin slice, not more than 1.25 cm., should be removed from the upper end of the tibia. If any diseased tissue appears still to be left in the bones, it should be removed with the gouge, rather than by a further section.

The bursa about the knee-joint are sometimes the seat of enlargement. The bursa between the front of the patella and the skin is frequently affected in individuals who are in the habit of constantly kneeling, and the condition is then known as 'housemaid's knee.' The bursa beneath the Semimembranosus tendon also occasionally becomes enlarged, and forms a fluctuating swelling at the back of the knee. During extension, the swelling is firm and tense; but during flexion it becomes soft, and, as the bursa often communicates with the synovial cavity of the joint, the fluid it contains can be made to disappear by pressure when the knee is flexed. Extension of septic processes within the joint is apt to occur along the tendon-sheath of the Popliteus, and this may lead to deep-seated suppuration in the popliteal fossa, often associated with septic thrombosis of the popliteal vein: when this occurs amputation of the limb is necessary.

V. ARTICULATIONS BETWEEN THE TIBIA AND FIBULA

The articulations between the tibia and fibula are effected by ligaments which connect the extremities and bodies of the bones. The ligaments may consequently be subdivided into three sets: (1) those of the proximal tibiofibular articulation; (2) the crural interosseous membrane; (3) those of the distal tibiofibular articulation (tibiofibular syndesmosis).

1. PROXIMAL TIBIOFIBULAR ARTICULATION (fig. 502)

This articulation is an arthrodial joint between the lateral condyle of the tibia and the head of the fibula. The contiguous surfaces of the bones present flat, oval facets covered with cartilage and connected together by an articular capsule and by anterior and posterior ligaments.

The **articular capsule** envelops the articulation, being attached round the margins of the articular facets on the tibia and fibula: it is much thicker in front than behind. Occasionally the synovial stratum of the capsule is continuous with that of the knee-joint.

The **anterior ligament** of the head of the fibula consists of two or three flat bands, which pass obliquely upwards from the front of the head of the fibula to the front of the lateral condyle of the tibia.

The **posterior ligament** of the head of the fibula is a thick band, which passes obliquely upwards from the back of the head of the fibula to the back of the lateral condyle of the tibia. It is covered by the tendon of the Popliteus.

2. CRURAL INTEROSSEOUS MEMBRANE

The **crural interosseous membrane** connects the interosseous crests of the tibia and fibula, and separates the muscles on the front from those on the back of the leg. It consists of oblique fibres, which for the most part run downwards and lateralwards; a few, however, pass in the opposite direction. The anterior tibial vessels pass above its upper margin; in its lower part is an opening for the passage of the anterior peroneal vessels. It is continuous below with the interosseous ligament of the tibiofibular syndesmosis, and presents numerous perforations for the passage of small vessels. It is in

relation, in front, with the *Tibialis anterior*, *Extensor digitorum longus*, *Extensor hallucis longus*, *Peronæus tertius*, and the anterior tibial vessels and deep peronæal nerve; behind, with the *Tibialis posterior* and *Flexor hallucis longus*.

3. DISTAL TIBIOFIBULAR ARTICULATION (TIBIOFIBULAR SYNDESMOSIS)

This syndesmosis is formed by the rough, convex surface of the medial side of the lower end of the fibula, and a rough concave surface, the fibular notch, on the lateral side of the tibia. Below, to the extent of about 4 mm., these surfaces are smooth, and covered with cartilage, continuous with that of the ankle-joint. The ligaments are: anterior, posterior, inferior transverse, and interosseous.

FIG. 507.—Articular capsule of left talocrural articulation (distended).
Lateral aspect.

The **anterior ligament** of the lateral malleolus (fig. 510) is a triangular band, broader below than above, which extends obliquely downwards and lateralwards between the adjacent margins of the tibia and fibula, on the front of the syndesmosis.

The **posterior ligament** of the lateral malleolus (fig. 508), smaller than the preceding, is disposed in a similar manner on the posterior surface of the syndesmosis. Its deep portion forms the **inferior transverse ligament**, a strong, thick band of yellowish fibres which passes transversely across the back of the joint, from the lateral malleolus to the posterior border of the articular surface of the tibia, almost as far as its malleolar process. The inferior transverse ligament projects below the margins of the bones, and forms part of the articulating surface for the talus.

The **interosseous ligament** is continuous, above, with the interosseous membrane and consists of numerous short, strong bands, which pass between the adjacent rough surfaces of the tibia and fibula, and constitute the chief bond of union between the bones.

The **synovial stratum** associated with the small arthrodial part of this joint is continuous with that of the ankle-joint.

VI. TALOCRURAL ARTICULATION OR ANKLE-JOINT

The ankle-joint is a ginglymus, or hinge-joint. Entering into its formation are the lower end of the tibia and its malleolus, the malleolus of the fibula, and the inferior transverse tibiofibular ligament, which together form a mortise for the reception of the trochlea of the talus. The bones are connected by the following ligaments :

The articular capsule.
Deltoid.

Anterior talofibular.
Posterior talofibular.

Calcaneofibular.

The articular capsule (fig. 507) surrounds the joint, and its fibrous stratum is attached, above, to the borders of the articular surfaces of the tibia

FIG. 508.—Left talocrural articulation, from behind.

and malleoli, and below, to the talus around its trochlear articular surface. Its anterior part, often termed the *anterior ligament*, is a broad, thin, membranous layer, attached, above, to the anterior margin of the lower end of the tibia, and below, to the talus, in front of its superior articular surface. It is in relation, in front, with the extensor tendons of the toes, the tendons of the Tibialis anterior and Peronæus tertius, and the anterior tibial vessels and deep peronæal nerve. Its posterior part, often termed the *posterior ligament*, is very thin, and consists principally of transverse fibres. It is attached, above, to the margin of the articular surface of the tibia, blending with the inferior transverse ligament, and below, to the talus behind its superior articular facet. Laterally, it is somewhat thickened, and is attached to the hollow on the medial surface of the lateral malleolus.

The fibrous stratum is lined by a synovial stratum, and the joint-cavity is continued upwards for a short distance between the tibia and fibula.

The *deltoid ligament* (internal lateral ligament) (figs. 508, 509) is a strong, triangular band, attached, above, to the apex and anterior and posterior borders of the medial malleolus. It consists of two sets of fibres, superficial and deep,

Of the superficial fibres the anterior (*tibionavicular*) pass forwards to be attached to the tuberosity of the navicular bone, and immediately behind this they blend with the medial margin of the plantar calcaneonavicular ligament; the middle (*calcaneotibial*) descend almost perpendicularly and are fixed into the whole length of the sustentaculum tali of the calcaneus; the posterior fibres (*posterior talotibial*) pass backwards and lateralwards to be attached to the medial side of the talus, and to the prominent tubercle on its posterior surface, medially to the groove for the tendon of the Flexor hallucis longus. The deep fibres (*anterior talotibial*) are fixed, above, to the tip of the medial malleolus, and, below, to the medial surface of the talus. The deltoid ligament is crossed by the tendons of the Tibialis posterior and Flexor digitorum longus.

FIG. 509.—Ligaments of ankle and tarsus. Medial aspect.

The **anterior talofibular ligament** (fig. 510) passes from the anterior margin of the fibular malleolus, forwards and medialwards, to the talus, in front of its lateral articular facet.

The **posterior talofibular ligament** (fig. 508), strong and deeply seated, runs almost horizontally from the depression at the medial and posterior part of the fibular malleolus to the posterior process of the talus.

The **calcaneofibular ligament** (fig. 510) is a long rounded cord, running from the apex of the fibular malleolus downwards and slightly backwards to a tubercle on the lateral surface of the calcaneus. It is covered by the tendons of the Peronæi longus and brevis.

The anterior and posterior talofibular and the calcaneofibular ligaments were formerly described as the three fasciculi of the *external lateral ligament* of the ankle-joint.

Relations.—The tendons, vessels, and nerves in relation with the joint are, in front, from the medial side, the Tibialis anterior, Extensor hallucis longus, anterior tibial vessels, deep peronæal nerve, Extensor digitorum longus, and Peronæus tertius; behind, from the medial side, the Tibialis posterior, Flexor digitorum longus, posterior tibial vessels, tibial nerve, Flexor hallucis longus; and, in the groove behind the fibular malleolus, the tendons of the Peronæi longus and brevis.

The *arteries* supplying the joint are derived from the malleolar branches of the anterior tibial and from the peronæal.

The *nerves* are derived from the deep peronæal and tibial.

Movements.—When the body is in the erect position, the foot is at right angles to the leg. The movements of the joint are those of dorsiflexion and extension; dorsiflexion consists in the approximation of the dorsum of the foot to the front of the leg, while in extension the heel is drawn up and the toes pointed downwards. The malleoli tightly embrace the talus in all positions of the joint, so that any slight degree of side-to-side movement which may exist is simply due to stretching of the ligaments of the talofibular syndesmosis, and slight bending of the body of the fibula. The superior articular surface of the talus is broader in front than behind. In dorsiflexion, therefore, greater space is required between the two malleoli. This is obtained by a slight outward rotatory movement of the lower end of the fibula and a stretching of the ligaments of the syndesmosis; this lateral

FIG. 510.—Ligaments of ankle and tarsus. Lateral aspect.

movement is facilitated by a slight gliding at the tibiofibular articulation, and possibly also by the bending of the body of the fibula. Of the ligaments, the deltoid is of great power—so much so, that it usually resists a force which fractures the process of bone to which it is attached. Its middle portion, together with the calcaneofibular ligament, binds the bones of the leg firmly to the foot, and resists displacement in every direction. Its anterior and posterior fibres limit extension and flexion of the foot respectively, and the anterior fibres also limit abduction. The posterior talofibular ligament assists the calcaneofibular in resisting the displacement of the foot backwards, and deepens the cavity for the reception of the talus. The anterior talofibular ligament is a security against the displacement of the foot forwards, and limits extension of the joint.

Extension of the foot upon the tibia and fibula is produced by the Gastrocnemius, Soleus, Plantaris, Tibialis posterior, Peronæi longus and brevis, Flexor digitorum longus, and Flexor hallucis longus; *dorsiflexion*, by the Tibialis anterior, Peronæus tertius, Extensor digitorum longus, and Extensor hallucis longus.*

Applied Anatomy.—As the ankle-joint is a very strong and powerful articulation, displacement of the talus from the tibiofibular mortise is a rare accident, and great force

* The student must bear in mind that the Extensor digitorum longus and Extensor hallucis longus are *extensors* of the toes, but *flexors* of the ankle; and that the Flexor digitorum longus and Flexor hallucis longus are *flexors* of the toes, but *extensors* of the ankle.

is required to produce it. Nevertheless, dislocation does occasionally occur, either anteroposteriorly or to one or other side. In the latter, which is the more common, fracture is a necessary accompaniment of the injury. The dislocation in these cases is somewhat peculiar, and is not a displacement in a horizontal direction, such as usually occurs in dislocations of ginglymoid joints, but the talus undergoes a partial rotation round an anteroposterior axis drawn through its own centre, so that the superior surface, instead of being directed upwards, is inclined more or less medialwards or lateralwards according to the variety of the displacement.

The ankle-joint is more frequently sprained than any joint in the body, and this may lead to acute synovitis. In these cases, when the synovial sac is distended with fluid, the bulging appears principally in the front of the joint, beneath the anterior tendons, and on either side, between the Tibialis anterior and the deltoid ligament on the medial side, and between the Peroneus tertius and the anterior talofibular ligament laterally. In addition to this, bulging often occurs posteriorly, and a fluctuating swelling may be detected on either side of the tendo calcaneus. A large proportion of so-called 'sprains' of the ankle have been proved by x-ray examination to be some variety of fracture about the malleoli, with or without displacement.

Chronic synovitis may result from frequent sprains, and when once this joint has been sprained it is liable to a recurrence of the injury; or the synovitis may be tuberculous in its origin, the disease usually beginning in the talus and extending to the joint, though it may commence in the synovial stratum of the articular capsule, the result probably of some slight strain in a tuberculous subject.

Excision of the ankle-joint is not often performed, since the foot after excision is often of very little use; far less useful, in fact, than after Syme's amputation, which is, therefore, a preferable operation in these cases. Further, disease of the ankle-joint is frequently associated with disease of the tarsal bones.

VII. INTERTARSAL ARTICULATIONS

1. TALOCALCANEAL ARTICULATION

The articulations between the calcaneus and talus are two in number— anterior and posterior. Of these, the anterior forms part of the talocalcaneonavicular joint, and will be described with that articulation. The posterior or talocalcaneal articulation is formed between the posterior calcaneal facet on the inferior surface of the talus, and the posterior facet on the superior surface of the calcaneus. It is an arthrodial joint, and the two bones are connected by an articular capsule and by anterior, posterior, lateral, medial, and interosseous talocalcaneal ligaments.

The **articular capsule** envelops the joint, and consists for the most part of short fibres; it is split up into distinct slips, and between these there is only a weak fibrous investment. It is lined by a synovial stratum, and the joint-cavity does not communicate with any of the other tarsal joints.

The **anterior talocalcaneal ligament** (fig. 513) extends from the front and lateral surface of the neck of the talus to the superior surface of the calcaneus.

The **posterior talocalcaneal ligament** (fig. 509) connects the lateral tubercle on the posterior surface of the talus with the upper and medial part of the calcaneus; it is a short band, and its fibres radiate from their narrow attachment to the talus.

The **lateral talocalcaneal ligament** (figs. 507, 510) is a short, strong fasciculus, passing from the lateral surface of the talus, immediately beneath its fibular facet, to the lateral surface of the calcaneus. It is placed in front of, but on a deeper plane than, the calcaneofibular ligament, with the fibres of which it is parallel.

The **medial talocalcaneal ligament** connects the medial tubercle on the posterior surface of the talus with the back of the sustentaculum tali. Its fibres blend with those of the plantar calcaneonavicular ligament.

The **interosseous talocalcaneal ligament** (figs. 507, 511) is very thick and strong, and forms the chief bond of union between the bones. It is, in fact, a portion of the united capsules of the talocalcaneonavicular and the talocalcaneal joints, and consists of two partially united layers of fibres, one belonging to the former and the other to the latter joint. It is attached, above, to the sulcus tali; below, to the sulcus calcanei.

Movements.—The movements permitted between the talus and calcaneus are limited to gliding of the one bone on the other, backwards and forwards and from side to side.

2. TALOCALCANEONAVICULAR ARTICULATION

This articulation is an arthrodial joint: the rounded head of the talus being received into the concavity formed by the posterior surface of the navicular bone, the anterior articular surface of the calcaneus, and the upper surface of the plantar calcaneonavicular ligament. There are two ligaments in this joint; the articular capsule and the talonavicular.

The **articular capsule** is imperfectly developed except posteriorly, where it is considerably thickened and forms, with a part of the capsule of the talocalcaneal joint, the strong interosseous ligament which fills the sinus tarsi formed by the opposing sulci on the calcaneus and talus, as above mentioned.

FIG. 511.—Coronal section through right talocrural and talocalcaneal joints.

The **talonavicular ligament** (fig. 509) is a broad, thin band, connecting the neck of the talus to the dorsal surface of the navicular bone; it is covered by the Extensor tendons. The plantar calcaneonavicular supplies the place of a plantar ligament for this joint.

Movements.—This articulation permits of a considerable range of gliding movements.

3. CALCANEOCUBOID ARTICULATION

The ligaments connecting the calcaneus with the cuboid bone are five in number, viz. the articular capsule, the dorsal calcaneocuboid, the calcaneocuboid part of the bifurcated ligament, the long plantar, and the plantar calcaneocuboid.

The **articular capsule** contains certain bands, which form the other ligaments of the joint. Its synovial stratum is distinct from that of the other tarsal articulations (fig. 514):

The **dorsal calcaneocuboid ligament** (fig. 510) is a thin but broad fasciculus, which passes between the contiguous surfaces of the calcaneus and the cuboid bone, on the dorsal surface of the joint.

The **bifurcated ligament** (figs. 510, 513) is a strong band attached behind to the deep hollow on the upper surface of the calcaneus and dividing in front in a Y-shaped manner into a calcaneocuboid and a calcaneonavicular part. The *calcaneocuboid part* is fixed to the medial side of the cuboid bone and forms one of the principal bonds between the first and second rows of the tarsal bones. The *calcaneonavicular part* is attached to the lateral side of the navicular bone.

The **long plantar ligament** (fig. 512), the longest of the tarsal ligaments, is attached behind to the plantar surface of the calcaneus in front of the tuberosity, and in front to the tuberosity on the plantar surface of the cuboid bone, the more superficial fibres being continued forwards to the bases of the second, third, and fourth metatarsal bones. This ligament converts the groove on the plantar surface of the cuboid bone into a canal for the tendon of the Peronæus longus.

FIG. 512.—Ligaments of plantar surface of the right foot.

The **plantar calcaneocuboid ligament** (fig. 512) lies nearer to the bones than the preceding, from which it is separated by a little areolar tissue. It is a short but wide band of great strength, and extends from the tubercle and the depression in front of it, on the fore part of the plantar surface of the calcaneus, to the plantar surface of the cuboid bone behind the peroneal groove.

Movements. The movements permitted between the calcaneus and the cuboid bone are limited to slight gliding of the bones upon each other.

The *transverse tarsal joint* is formed by the articulation of the calcaneus with the cuboid bone, and the articulation of the talus with the navicular bone. The movement which takes place in this joint is more extensive than that in the other tarsal joints, and consists of a sort of rotation by means of which the foot may be slightly flexed or extended, the sole being at the same time carried medialwards (inverted) or lateralwards (everted).

4. LIGAMENTS CONNECTING THE CALCANEUS AND NAVICULAR

Though the calcaneus and the navicular bones do not directly articulate, they are connected by two ligaments: the calcaneonavicular part of the bifurcated, and the plantar calcaneonavicular.

The calcaneonavicular part of the bifurcated ligament is described above.

The **plantar calcaneonavicular ligament** (fig. 513) is a broad, thick band connecting the anterior margin of the sustentaculum tali of the calcaneus to the plantar surface of the navicular bone. This ligament not only unites the calcaneus with the navicular bone, but supports the head of the talus, forming part of the articular cavity in which it is received. The *dorsal surface* of the ligament presents a fibrocartilaginous facet, lined by the synovial stratum, and upon this a portion of the head of the talus rests. Its *plantar surface* is supported by the tendon of the Tibialis posterior; its *medial border* is blended with the anterior part of the deltoid ligament of the ankle-joint. The plantar calcaneonavicular and plantar calcaneocuboid ligaments together form the *deep ligament* of the tarsus.

Applied Anatomy.—The plantar calcaneonavicular ligament, by supporting the head of the talus, is concerned in maintaining the arch of the foot. When it yields the head of the talus is pressed downwards, medialwards, and forwards by the weight of the body, and the foot becomes flattened, expanded, and turned lateralwards, and exhibits the condition known as *flat-foot*. This ligament contains a considerable amount of elastic tissue, so as to give elasticity to the arch and spring to the foot; hence it is sometimes called the 'spring' ligament. It is supported, on its plantar surface, by the tendon of the Tibialis posterior, which spreads out at its insertion into a number of fasciculi, to be attached to most of the tarsal and metatarsal bones. This prevents undue stretching of the ligament, and is a protection against the occurrence of flat-foot; hence muscular weakness is, in most cases, the primary cause of the deformity.

FIG. 513. - Talocalcaneal and talocalcaneonavicular articulations exposed from above by removing the talus.

5. CUNEONAVICULAR ARTICULATION.

The navicular bone is connected to the three cuneiform bones by dorsal and plantar ligaments.

The **dorsal ligaments** are three small fasciculi, one attached to each of the cuneiform bones. The fasciculus connecting the navicular bone with the first cuneiform bone is continuous round the medial side of the articulation with the plantar ligament which unites these two bones.

The **plantar ligaments** have a similar arrangement to the dorsal, and are strengthened by slips from the tendon of the Tibialis posterior.

Movements.—Gliding movements are permitted between the navicular and cuneiform bones.

6. CUBOIDCUNEONAVICULAR ARTICULATION

The cuboid bone is connected with the navicular bone by dorsal, plantar, and interosseous ligaments.

The **dorsal ligament** extends obliquely forward and lateralwards, while the **plantar** passes nearly transversely from the cuboid bone to the navicular bone.

The **interosseous ligament** consists of strong transverse fibres, and connects the rough non-articular portions of the adjacent surfaces of the two bones.

Movements.—The movements permitted between the navicular and cuboid bones are limited to a slight gliding upon each other.

7. INTERCUNEIFORM AND CUNEOCUBOID ARTICULATIONS

The three cuneiform bones and the cuboid bone are connected together by dorsal, plantar, and interosseous ligaments.

The **dorsal and plantar ligaments** each consist of three transverse bands: one connects the first and second cuneiform bones, another the second and third cuneiform bones, and another the third cuneiform and cuboid bones. The **plantar ligaments** are strengthened by slips from the tendon of the Tibialis posterior.

The **interosseous ligaments** connect the rough non-articular portions of the adjacent surfaces of the bones.

Movements.—The movements permitted between these bones are limited to a slight gliding upon each other.

Applied Anatomy.—In spite of the great strength of the ligaments which connect the tarsal bones together, dislocation at some of the tarsal joints does occasionally occur. When this takes place, it is most commonly in connexion with the talus; for not only may this bone be dislocated from the tibia and fibula at the ankle-joint, but the other bones may be dislocated from it, the talus remaining *in situ* in the tibiofibular mortise. This constitutes what is known as the *subtalar* dislocation. Or, again, the talus may be dislocated from all its connexions—from the tibia and fibula above, the calcaneus below, and the navicular in front—and may even undergo a rotation, on either a vertical or a horizontal axis. In the former case the long axis of the bone is directed across the joint, so that the head faces the articular surface on one or other malleolus; in the latter, the collateral surfaces are directed upwards and downwards, so that the superior surface faces to one or the other side. Reduction in these cases is often very difficult or impossible, and the displaced talus may require removal by open operation. Dislocation may also occur at the transverse tarsal joint, the anterior tarsal bones being luxated from the talus and calcaneus. The other tarsal bones are occasionally, though rarely, dislocated from their connexions.

VIII. TARSOMETATARSAL ARTICULATIONS

These are arthrodial joints. The bones entering into their formation are the first, second, and third cuneiform, and the cuboid, and they articulate with the bases of the metatarsal bones. The first metatarsal bone articulates with the first cuneiform bone; the second is deeply wedged in between the first and third cuneiform bones, articulating by its base with the second cuneiform bone; the third articulates with the third cuneiform bone; the fourth, with the cuboid and third cuneiform bones; and the fifth with the cuboid bone. The bones are connected by dorsal, plantar, and interosseous ligaments.

The **dorsal ligaments** are strong, flat bands. The first metatarsal is joined to the first cuneiform bone by an articular capsule; the second has three bands, one from each cuneiform bone; the third has one from the third cuneiform bone; the fourth has one from the third cuneiform bone and one from the cuboid bone; and the fifth, one from the cuboid bone.

The **plantar ligaments** consist of longitudinal and oblique bands, disposed with less regularity than the dorsal ligaments. Those for the first and second metatarsal bones are the strongest; the second and third metatarsal bones are joined by oblique bands to the first cuneiform bone; the fourth and fifth metatarsal bones are connected by a few fibres to the cuboid bone.

The **interosseous ligaments** are three in number. The first is the strongest and passes from the lateral surface of the first cuneiform bone to the adjacent angle of the second metatarsal bone. The second connects the third cuneiform bone with the adjacent angle of the second metatarsal bone. The third connects the lateral angle of the third cuneiform bone with the adjacent side of the base of the third metatarsal bone.

Movements.—The movements permitted between the tarsal and metatarsal bones are limited to slight gliding of the bones upon each other.

Nerve Supply.—The intertarsal and tarsometatarsal joints are supplied by the deep peroneal nerve.

IX. INTERMETATARSAL ARTICULATIONS

The base of the first metatarsal bone is not connected with that of the second by any ligaments; in this respect the great toe resembles the thumb.

The bases of the second, third, fourth, and fifth metatarsal bones are connected by dorsal, plantar, and interosseous ligaments.

The heads of all the metatarsal bones are connected by the transverse metatarsal ligament.

The **dorsal and plantar ligaments** pass transversely between the bases of the adjacent bones.

The **interosseous ligaments** consist of strong transverse fibres which connect the rough non-articular portions of the adjacent surfaces.

The **transverse metatarsal ligament** is a narrow band which runs across and connects together the heads of all the metatarsal bones; it is blended anteriorly with the accessory plantar ligaments of the metatarsophalangeal articulations. Its plantar surface is concave where the flexor tendons run

FIG. 514.—Oblique section of left intertarsal and tarsometatarsal articulations, showing the synovial cavities.

below it; above it the tendons of the Interossei pass to their insertions. It differs from the transverse metacarpal ligament in that it connects the first metatarsal to the others.

Movements.—The movements permitted between the tarsal ends of the metatarsal bones are limited to a slight gliding of the articular surfaces one upon another.

The **synovial cavities** (fig. 514) present in the articulations of the tarsus and metatarsus are six in number: one for the talocalcaneal articulation; a second for the talocalcaneonavicular articulation; a third for the calcaneo-cuboid articulation; a fourth for the cuneonavicular, intercuneiform, and cuneocuboid articulations, the articulations of the second and third cuneiform bones with the bases of the second and third metatarsal bones, and the adjacent surfaces of the base of the second, third, and fourth metatarsal bones; a fifth for the first cuneiform bone with the metatarsal bone of the great toe; and a sixth, for the articulation of the cuboid bone with the fourth and fifth metatarsal bones. A small synovial cavity is sometimes found between the contiguous surfaces of the navicular and cuboid bones.

X. METATARSOPHALANGEAL ARTICULATIONS

The metatarsophalangeal articulations are of the condyloid kind, formed by the reception of the rounded heads of the metatarsal bones in shallow cavities on the bases of the first phalanges.

The ligaments are the accessory plantar and collateral.

The **accessory plantar ligaments** (glenoid ligaments of Cruveilhier) are thick, dense, fibrous structures. They are placed on the plantar surfaces of the joints in the intervals between the collateral ligaments, to which they are connected; they are loosely united to the metatarsal bones, but very firmly to the bases of the first phalanges. Their plantar surfaces are intimately blended with the transverse metatarsal ligament, and grooved for the flexor tendons, the sheaths surrounding which are connected to the sides of the grooves; their deep surfaces form parts of the articular facets for the heads of the metatarsal bones.

The **collateral ligaments** are two strong, rounded cords, placed on the sides of the joints; each is attached by one end to the posterior tubercle on the side of the head of the metatarsal bone, and by the other to the contiguous extremity of the phalanx.

The place of *dorsal ligaments* is supplied by the extensor tendons on the dorsal surfaces of the joints.

Movements.—The movements permitted in the metatarsophalangeal articulations are flexion, extension, adduction, and abduction.

XI. ARTICULATIONS OF THE DIGITS

The interphalangeal articulations are ginglymoid joints and each has a plantar and two collateral ligaments.

The arrangement of the ligaments is similar to that in the metatarsophalangeal articulations: the extensor tendons supply the places of dorsal ligaments.

Movements.—The only movements permitted in the joints of the digits are flexion and extension; these movements are more extensive between the first and second phalanges than between the second and third. The amount of flexion is very considerable, but extension is limited by the plantar and collateral ligaments.

Applied Anatomy.—Gout peculiarly affects the metatarsophalangeal joint of the big toe, beginning with the deposit of sodium and calcium urates in the articular cartilages. Later the circumarticular fibrous tissue becomes the seat of these gouty deposits, and considerable thickening and deformity may result.

Chronic arthritis with much enlargement of the head of the first metatarsal bone is often seen, giving rise to stiffness and pain on walking. The condition is termed *hallux rigidus*, and if, as frequently happens, it is accompanied by a displacement of the proximal phalanx lateralwards on the head of the metatarsal bone, *hallux valgus* is the resulting condition. The latter is commonly associated with the development of a bunion on the medial aspect of the thickened metatarsal head, while the second toe becomes contracted and deformed and assumes the condition known as *hammer toe*. This is especially the case if the individual has been in the habit of wearing tightly fitting boots, more particularly if the medial margin of the sole slopes lateralwards. The hammer toe deformity consists of an extreme flexion of the proximal interphalangeal joint with a hyperextension of the distal joint, and the big toe lies either on the dorsal or plantar aspect of the second toe.

Septic arthritis of the first metatarsophalangeal joint is seen in association with perforating ulcer of the foot, not uncommon in diabetes or locomotor ataxia.

ARCHES OF THE FOOT

In order that it may support the weight of the body in the erect posture with the least expenditure of material, the foot is constructed of a series of arches formed by the tarsal and metatarsal bones, and strengthened by the ligaments and tendons of the foot.

The main arches are the anteroposterior arches, which may be regarded as divisible into two types—a medial and a lateral.

The *medial arch* (fig. 515) is made up by the calcaneus, the talus, the navicular, the three cuneiform, and the first, second, and third metatarsal bones. Its summit is at the superior articular surface of the talus, and its two extremities or piers,

on which it rests in standing, are the tuberosity on the plantar surface of the calcaneus posteriorly, and the heads of the first, second, and third metatarsal bones anteriorly. The chief characteristic of this arch is its elasticity, due to its height and to the number of joints between its component parts. Its weakest part, i.e. the part most liable to yield from over-pressure, is the joint between the talus and the navicular bone, but this is braced by the plantar calcaneonavicular ligament, which is elastic and is thus able quickly to restore the arch to its pristine condition when the disturbing force is removed. This ligament is strengthened medially by blending with the deltoid ligament of the ankle-joint, and is supported inferiorly by the tendon of the *Tibialis posterior*. The arch is further supported by the

FIG. 515.—Skeleton of foot. Medial aspect.

FIG. 516.—Skeleton of foot. Lateral aspect.

plantar aponeurosis, by the small muscles in the sole of the foot, by the tendons of the *Tibialis anterior* and *Peronæus longus*, and by the ligaments of all the articulations involved.

The *lateral arch* (fig. 516) is composed of the calcaneus, the cuboid, and the fourth and fifth metatarsal bones. Its summit is at the talocalcaneal articulation, and its chief joint is the calcaneocuboid, which possesses a special mechanism for locking, and allows only a limited movement. The most marked features of this arch are its solidity and its slight elevation; two strong ligaments, the long plantar and the plantar calcaneocuboid, together with the extensor tendons and the short muscles of the little toe, preserve its integrity.

While the medial and lateral arches may be readily demonstrated, as the component anteroposterior arches of the foot, yet the *fundamental longitudinal arch* is contributed to by both, and consists of the calcaneus, cuboid, third cuneiform, and third metatarsal bones: all the other bones of the foot may be removed without destroying this arch.

In addition to the longitudinal arches the foot presents a series of transverse arches. At the posterior part of the metatarsus and the anterior part of the tarsus the arches are complete, but in the middle of the tarsus they present more the characters of half-domes the concavities of which are directed downwards and medialwards, so that when the medial borders of the feet are placed in apposition a

complete tarsal dome is formed. The transverse arches are strengthened by the interosseous, plantar, and dorsal ligaments, by the short muscles of the first and fifth toes (especially the transverse head of the Adductor hallucis), and by the Peronæus longus, whose tendon stretches between the piers of the arches.

Applied Anatomy.—*Pes planus* or flat-foot is a very common deformity due to the disappearance of the arches of the foot from subsidence dependent on stretching of the plantar ligaments. In its early stages before the deformity is marked it is accompanied by considerable pain from pressure on the plantar nerves, but when the condition is fully formed and the head of the talus has descended completely, the condition is painless but irremediable.

The stretching of the ligaments in this condition is most often due to muscular weakness in young adults who may have to stand for long periods daily. The deep muscles, especially the posterior tibial group, by their tonicity are the most potent in maintaining the longitudinal arch, and when overtired they relax and throw the strain on the plantar ligaments which yield secondarily. All three posterior tibial muscles are effective in thus supporting the longitudinal arch, but perhaps the most important one is the Flexor hallucis longus which normally stretches like a bow-string across the whole antero-posterior length of the arch.

The transverse arch subsequently disappears, this having been largely held up by the Peronæus longus. In the treatment of this static form of flat-foot, muscular rest is essential in the early stages, as once the ligamentous tissues are stretched, they are unable to return to their original condition.

There are, however, other forms of flat-foot, viz. the congenital, and the paralytic (due to affections of the centres supplying the post-tibial group of muscles); those due to inflammation of the tarsal joints and those following injuries to the tarsus and metatarsus. If in the two latter forms the patient put his weight on the foot before the normal condition has been fully established, *pes planus* is certain to result, and the arches will not be capable of restoration subsequently.

Pes cavus, the opposite of *pes planus*, is usually due to some contracture of the posterior tibial group in certain affections of the medulla spinalis. It is also commonly seen in association with talipes equinus or equinovarus, and here the longitudinal arching of the foot is greatly increased, with contraction of the plantar aponeurosis which in some instances becomes very pronounced.

MYOLOGY*

THE Muscles are connected with the bones, cartilages, ligaments, and skin, either directly, or through the intervention of fibrous structures called tendons or aponeuroses. Where a muscle is attached to bone or cartilage, the fibres end in blunt extremities upon the periosteum or perichondrium, and do not come into direct relation with the osseous or cartilaginous tissue. Where muscles are connected with the skin, they lie as a flattened layer beneath it, and are united with its areolar tissue by larger or smaller bundles of fibres.

Muscles vary in their form. In the limbs, they are of considerable length, especially the more superficial ones; they surround the bones, and constitute an important protection to the joints. In the trunk, they are broad and flattened, and assist in forming the walls of the trunk cavities. Hence the reason of the terms, *long*, *broad*, *short*, &c., used in the description of muscles.

There is considerable variation in the arrangement of the fibres of certain muscles with reference to the tendons to which they are attached. In some muscles the fibres are parallel and run directly from their origin to their insertion; these are quadrilateral muscles, such as the Thyreo-hyoideus. A modification of these is found in the fusiform muscles, in which the fibres are not quite parallel, but slightly curved, so that the muscle tapers at either end; in their mode of action, however, they resemble the quadrilateral muscles. In other muscles the fibres arise by a broad origin and converge to a narrow or pointed insertion; this arrangement is found in the triangular muscles—e.g. the Temporalis. In some muscles, which otherwise would belong to the quadrilateral or triangular type, the origin and insertion are not in the same plane, the plane of the line of origin intersecting that of the line of insertion: such is the case in the Pectineus. In some muscles (e.g. the Peronæi) the fibres are oblique and are attached to one side of a tendon; such muscles are termed unipennate. A modification of this condition is found where oblique fibres are fixed to both sides of a central tendon; such muscles are called bipennate, and an example is afforded in the Rectus femoris. Finally, there are muscles in which the fibres are arranged in curved bundles in one or more planes, as in the Sphincters. The arrangement of the fibres is of considerable importance in respect to the relative strength and range of movement of the muscle. Those muscles where the fibres are long and few in number have great range, but diminished strength; where, on the other hand, the fibres are short and more numerous, there is great power, but lessened range.

The names applied to the various muscles have been derived: 1, from their situation, as the Tibialis anterior, Tibialis posterior; 2, from their direction, as the Rectus abdominis, Obliqui capitis, Transversus abdominis; 3, from their uses, as Flexors, Extensors, Abductors, &c.; 4, from their shape, as the Deltoides, Rhomboideus; 5, from the number of their divisions, as the Biceps, and Triceps; 6, from their attachment, as the Sternocleidomastoideus, Sternohyoideus, Sternothyroideus.

* The muscles and fasciæ are described conjointly, in order that the student may consider the arrangement of the latter in his dissection of the former. It is rare for the student of anatomy in this country to have the opportunity of dissecting the fasciæ separately; and it is for this reason, as well as from the close connexion that exists between the muscles and their investing sheaths, that they are considered together. Some general observations are first made on the anatomy of the muscles and fasciæ, the special descriptions being given in connexion with the different regions.

In the description of a muscle, the term *origin* is meant to imply its more fixed or central attachment; and the term *insertion* the movable point on which the force of the muscle is applied; but the origin is absolutely fixed in only a small number of muscles, such as those of the face which are attached by one extremity to immovable bones, and by the other to the movable integument; in the greater number, the muscle can be made to act from either extremity.

In the dissection of the muscles, attention should be directed to the exact *origin*, *insertion*, and *actions* of each, and to its more important *relations* with surrounding parts. While accurate knowledge of the points of attachment of the muscles is of great importance in determining their actions, it is not to be regarded as conclusive. The action of the muscle deduced from its attachments, or even by pulling on it in the dead subject, is not necessarily its action in the living. By pulling, for example, on the Brachioradialis in the cadaver the hand may be slightly supinated when in the prone position and slightly pronated when in the supine position, but there is no evidence that these actions are performed by the muscle during life. It is impossible for an individual to throw into action any one muscle; in other words, movements, not muscles, are represented in the central nervous system. To carry out a movement a definite combination of muscles is called into play, and the individual has no power either to leave out a muscle from this combination, or to add one to it. One (or more) muscle of the combination is the chief moving force; when this muscle passes over more than one joint, other muscles (synergic muscles) come into play to inhibit the movements not required; a third set of muscles (fixation muscles) fix the limb—i.e. in the case of the limb-movements—and also prevent disturbances of the equilibrium of the body generally. As an example, the movement of the closing of the fist may be considered: (1) the prime movers are the Flexores digitorum, Flexor pollicis longus, and the small muscles of the thumb; (2) the synergic muscles are the Extensores carpi, which prevent flexion of the wrist; while (3) the fixation muscles are the Biceps and Triceps brachii, which steady the elbow and shoulder. A further point which must be borne in mind in considering the actions of muscles is that in certain positions a movement can be effected by gravity, and in such a case the muscles acting are the antagonists of those which might be supposed to be in action. Thus in flexing the trunk when no resistance is interposed the Sacrospinales contract to regulate the action of gravity, and the Recti abdominis are relaxed.*

The minute anatomy of muscular tissue is described on pp. 30 to 34.

Applied Anatomy.—By a consideration of the actions of the muscles, the surgeon is able to explain the causes of displacement in various forms of fracture, and the causes which produce distortion in various deformities, and, consequently, to adopt appropriate treatment in each case. The relations, also, of some of the muscles, especially those in immediate apposition with the larger blood-vessels, and the surface markings they produce, should be remembered, as they form useful guides in the application of ligatures to those vessels. Degeneration of muscular tissue is important clinically, and is met with in two main conditions. In one, the degeneration is myopathic, or primary in the muscles themselves; in the other it is neuropathic, or secondary to some lesion of the nervous system—a hemorrhage into the brain, for example, or injury or inflammation of some part of the medulla spinalis or peripheral nerves. In either case more or less paralysis and atrophy of the affected muscles result. When the degeneration begins primarily in the muscles, however, it often happens that though the muscle-fibres waste away, their place is taken by fibrous and fatty tissue to such an extent that the affected muscles increase in volume, and actually appear to hypertrophy.

Ossification of muscular tissue as a result of repeated strain or injury is not infrequent. It is oftenest found about the tendon of the Adductor longus and Vastus medialis in horsemen, or in the Pectoralis major and Deltoideus of soldiers. It may take the form of exostoses firmly fixed to the bone—e.g. 'rider's bone' on the femur—or of layers or spicules of bone lying in the muscles or their fasciæ and tendons. Busse states that these bony deposits are preceded by a hemorrhagic myositis due to injury, the effused blood organising and being finally converted into bone. In the rarer disease, progressive myositis ossificans, there is an unexplained tendency for practically any of the voluntary muscles to become converted into solid and brittle bony masses which are completely rigid.

* Consult in this connexion the Croonian Lectures (1903) on 'Muscular Movements and their representation in the Central Nervous System,' by Charles E. Beever, M.D.

TENDONS, APONEUROSES, AND FASCIÆ

Tendons are white, glistening cords, varying in length and thickness, and devoid of elasticity. They consist almost entirely of white fibrous tissue, the fibrils of which have an undulating course parallel with each other and are firmly united together. They are very sparingly supplied with blood-vessels, the smaller tendons presenting in their interior no trace of them. Nerves supplying tendons end in what are known as neurotendinous spindles or organs of Golgi; these are described with the organs of the senses.

Aponeuroses are flattened or ribbon-shaped tendons, of a pearly-white colour, iridescent and glistening; they are only sparingly supplied with blood-vessels.

The tendons and aponeuroses connect the muscles with the movable structures, such as the bones and cartilages. Where the end of a muscle is continued directly into a tendon, the line of junction between the two is usually well-defined, but where the muscle meets the tendon obliquely, bundles of tendon fibres generally run for a variable distance into the substance of the muscle, so that the line of junction is irregular. Microscopic examination shows that, in either case, the tendon is subdivided into small bundles, corresponding in size and number with the fibres of the muscle. Each muscular fibre ends in a more or less rounded extremity covered by sarcolemma, and the fibres of each tendon bundle are intimately united with the sarcolemma covering the end of the muscular fibre. The mode of union is well shown when the muscle fibre has shrunk inside its sarcolemma.

The **fasciæ** are fibro-areolar or aponeurotic laminæ, of variable thickness and strength, found in all regions of the body, investing the softer and more delicate organs. During the process of development many of the cells of the mesoderm are differentiated into bones, muscles, vessels, &c.; the cells of the mesoderm which are not so utilised form an investment for these structures and are differentiated into the true skin and the fasciæ of the body. The fasciæ are subdivided into superficial and deep.

The *superficial fascia* is found immediately beneath the integument over almost the entire surface of the body. It connects the skin to the subjacent parts, and consists of fibro-areolar tissue, containing in its meshes pellicles of fat in varying quantity. It varies in thickness in different parts of the body; in the groin it is so thick that it may be subdivided into several laminæ. Beneath the fatty layer there is generally another layer of superficial fascia, almost devoid of adipose tissue, in which the trunks of the subcutaneous vessels and nerves and the superficial lymph-glands are found. Certain cutaneous muscles are situated in the superficial fascia, e.g. the *Platysma* and the muscles of the face. The superficial fascia is most distinct at the lower part of the abdomen, perinæum, and extremities; it is very thin in those regions where muscular fibres are inserted into the integument, as on the side of the neck, in the face, and around the anus. It is very dense in the scalp, palms of the hands, and soles of the feet, forming a fibrofatty layer, which binds the integument firmly to the underlying structures. It facilitates the movement of the skin, serves as a soft nidus for the passage of vessels and nerves to the skin, and retains the warmth of the body, since the fat contained in its areolæ is a bad conductor of heat.

The *deep fascia* is a dense, inelastic membrane, forming sheaths for the muscles, and in some cases affording them broad surfaces for attachment. It consists of shining tendinous fibres, placed parallel with one another, and connected together by other fibres disposed in a rectilinear manner. It forms a strong investment which not only binds down collectively the muscles in each region, but gives a separate sheath to each, as well as to the vessels and nerves. It assists the muscles in their actions by the degree of tension and pressure it makes upon their surfaces; in certain situations the degree of tension and pressure is regulated by muscles, as, for instance, by the *Tensor fasciæ latæ* and *Glutæus maximus* in the thigh, and the *Palmaris longus* in the hand. In the limbs, the fascia not only invests the limb, but gives off septa which separate the various muscles, and are attached to the periosteum: these prolongations of fasciæ are usually spoken of as intermuscular septa.

The fasciæ and muscles may be grouped into those of the head and neck; of the trunk; of the upper extremity; and of the lower extremity.

FASCIÆ AND MUSCLES OF THE HEAD

I. THE MUSCLE OF THE SCALP

Epicranius

The superficial fascia in the cranial region is a firm, fibrofatty layer, intimately adherent to the integument, and to the Epicranius and its tendinous aponeurosis; behind, it is continuous with the superficial fascia at the back of the neck: laterally, is prolonged over the temporal fascia.

FIG. 517.—Muscles of the head, face, and neck.

The **Epicranius** (*Occipitofrontalis*) (fig. 517) is a broad, musculo-fibrous layer, which covers the whole of one side of the vertex of the skull, from the occipital bone to the eyebrow. It consists of two parts, the *Occipitalis* and

the *Frontalis*, connected by an intervening tendinous aponeurosis, the *galea aponeurotica*.

The *Occipitalis*, thin and quadrilateral in form, arises by tendinous fibres from the lateral two-thirds of the superior nuchal line of the occipital bone, and from the mastoid part of the temporal. It ends in the *galea aponeurotica*.

The *Frontalis* is thin, of a quadrilateral form, and intimately adherent to the superficial fascia. It is broader than the *Occipitalis* and its fibres are longer and paler in colour. It has no bony attachments. Its medial fibres are continuous with those of the *Procerus*; its intermediate fibres blend with the *Corrugator* and *Orbicularis oculi*; and its lateral fibres are also blended with the latter muscle over the zygomatic process of the frontal bone. From these attachments the fibres are directed upwards, and join the *galea aponeurotica* below the coronal suture. The medial margins of the *Frontales* are joined together for some distance above the root of the nose; but between the *Occipitales* there is a considerable, though variable, interval, occupied by the *galea aponeurotica*.

The *galea aponeurotica* (epicranial aponeurosis) covers the upper part of the cranium; behind, it is attached, in the interval between the *Occipitales*, to the external occipital protuberance and highest nuchal lines of the occipital bone; in front, it forms a short and narrow prolongation between the *Frontales*. On either side it gives origin to the *Auriculares anterior* and *superior*; in this situation it loses its aponeurotic character, and is continued over the temporal fascia to the zygomatic arch. It is closely united to the integument by the firm, fibrofatty superficial fascia: it is connected to the pericranium by loose cellular tissue, which allows of the movement of the aponeurosis, the latter carrying with it the integument.

Nerves.—The *Occipitalis* is supplied by the posterior auricular branch of the facial nerve, and the *Frontalis* by the temporal branches of the same nerve.

Actions.—The *Occipitales* draw the scalp backwards; the *Frontales* raise the eyebrows and the skin over the root of the nose, and at the same time draw the scalp forwards, throwing the integument of the forehead into transverse wrinkles. By bringing alternately into action the *Occipitales* and *Frontales* the entire scalp may be moved backwards and forwards. In the ordinary action of the *Frontales*, the eyebrows are elevated, thus giving to the face the expression of surprise: if the action be exaggerated, the eyebrows are still further raised, and the skin of the forehead thrown into transverse wrinkles, as in the expression of fright or horror.

A thin muscular slip, the *Transversus nuchæ*, is present in about 25 per cent. of cases; it arises from the external occipital protuberance or from the superior nuchal line, either superficial or deep to the *Trapezius*; it is frequently inserted with the *Auricularis posterior*, but may join the posterior edge of the *Sternocleidomastoideus*.

Applied Anatomy.—From an anatomical point of view, the scalp consists of five layers, viz. the skin, subcutaneous tissue, *Epicranium* and its aponeurosis, subaponeurotic connective tissue, and pericranium. But from a surgical standpoint it is better to regard the first three of these structures as a single layer, since they are all intimately fused together, and when torn off in an accident, or turned down as a flap in a surgical operation, remain firmly connected to each other. In consequence of the dense character of the subcutaneous tissue, the amount of swelling which occurs as the result of inflammation is slight; and the edges of a wound which does not involve the *Epicranium* or its aponeurosis do not gape. The blood-vessels, also, which lie in this tissue, when wounded, do not contract and retract freely; and therefore the hæmorrhage from scalp wounds is often very considerable, but can always be arrested by pressure—a matter of great importance, as it is often very difficult or impossible to pick up with forceps a wounded vessel in the scalp.

The subaponeurotic connective tissue is, from a surgical point of view, of considerable importance. It is loose and lax, and is easily torn through; and hence, when the scalp is wounded, this is the tissue which is torn when the flap is separated from the parts beneath. The vessels are contained in the flap, and there is little risk of sloughing, unless the vitality of the part has been actually destroyed by the injury. In consequence of the loose nature of the subaponeurotic tissue, any septic inflammation is apt to assume a very diffuse form and spread over the skull, and, unless relieved by timely incisions, may lead to serious complications. Owing to the attachments of the aponeurosis to the zygomatic arch and highest nuchal line, subaponeurotic effusions sag down in these situations, but do not extend beyond to the infratemporal fossa, or into the neck; anteriorly, however, where there is no definite attachment to bone, the effusion will pass

the lacrimal ducts, but the majority are directly continuous with the palpebral part of the muscle and can be traced across the lids.

The *medial palpebral ligament* (*tendo oculi*), about 4 mm. in length and 2 mm. in breadth, is attached to the frontal process of the maxilla in front of the lacrimal groove. Crossing the lacrimal sac, it divides into two parts, upper and lower, each attached to the medial end of the corresponding tarsus. As the ligament crosses the lacrimal sac, an aponeurotic lamina is given off from its posterior surface; this expands over the sac, and is attached to the posterior lacrimal crest.

The *lateral palpebral raphe* is a much weaker structure than the medial palpebral ligament. It is attached to the margin of the frontosphenoidal process of the zygomatic bone, and passes medialwards to the lateral commissure of the eyelids, where it divides into two slips, which are fixed to the margins of the respective tarsi.

The **Corrugator** is a small pyramidal muscle, placed at the medial end of the eyebrow, beneath the Frontalis and Orbicularis oculi. It arises from the medial end of the superciliary arch; and its fibres pass upwards and lateralwards, between the palpebral and orbital portions of the Orbicularis oculi, and are inserted into the deep surface of the skin, above the middle of the orbital arch.

Nerves.—The Orbicularis oculi and Corrugator are supplied by the facial nerve.

Actions.—The Orbicularis oculi is the sphincter muscle of the eyelids. The palpebral portion acts involuntarily, closing the lids gently, as in sleep or in blinking; the orbital portion is subject to the will. When the entire muscle is brought into action, the skin of the forehead, temple, and cheek is drawn towards the medial angle of the orbit, and the eyelids are firmly closed. The skin thus drawn upon is thrown into folds, especially radiating from the lateral angle of the eyelids; these folds become permanent in old age, and form the so-called 'crow's feet.' The Levator palpebræ superioris is the direct antagonist of this muscle since it raises the upper eyelid and exposes the front of the bulb of the eye. The lacrimal part of the Orbicularis oculi draws the eyelids and the ends of the lacrimal canals medialwards, and applies them to the surface of the bulb of the eye, thus placing them in the most favourable situation for receiving the tears; it also compresses the lacrimal sac. The Corrugator draws the eyebrow downwards and medialwards, producing the vertical wrinkles of the forehead. It is the 'frowning' muscle, and may be regarded as the principal muscle in the expression of suffering.

III. MUSCLES OF THE NOSE (fig. 517)

Procerus.
Nasalis.

Depressor septi.
Dilatator naris posterior.

Dilatator naris anterior.

The **Procerus** (*Pyramidalis nasi*) is a small pyramidal slip arising by tendinous fibres from the fascia covering the lower part of the nasal bone and upper part of the lateral nasal cartilage; it is inserted into the skin over the lower part of the forehead between the two eyebrows, its fibres decussating with those of the Frontalis.

The **Nasalis** (*Compressor naris*) consists of two parts, transverse and alar. The *transverse part* arises from the maxilla, above and laterally to the incisive fossa; its fibres proceed upwards and medialwards, expanding into a thin aponeurosis which is continuous on the bridge of the nose with that of the muscle of the opposite side, and with the aponeurosis of the Procerus. The *alar part* is attached by one end to the greater alar cartilage, and by the other to the integument at the apex of the nose.

The **Depressor septi** arises from the incisive fossa of the maxilla; its fibres ascend to be inserted into the septum and back part of the ala of the nose. It lies between the mucous membrane and muscular structure of the lip.

The **Dilatator naris posterior** is placed partly beneath the Quadratus labii superioris. It arises from the margin of the nasal notch of the maxilla,

and from the lesser alar cartilages, and is inserted into the skin near the margin of the nostril.

The **Dilatator naris anterior** is a delicate fasciculus, passing from the greater alar cartilage to the integument near the margin of the nostril; it is situated in front of the preceding.

Nerves.—All the muscles of this group are supplied by the facial nerve.

Actions.—The **Procerus** draws down the medial angles of the eyebrows and produces transverse wrinkles over the bridge of the nose. The **Dilatatores** enlarge the apertures of the nares. Their action in ordinary breathing is to resist the tendency of the nares to close from atmospheric pressure, but in difficult breathing, as well as in some emotions, such as anger, they contract strongly. The **Depressor septi** is a direct antagonist of the other muscles of the nose, drawing the ala of the nose downwards, and thereby constricting the apertures of the nares. The **Nasalis** depresses the cartilaginous part of the nose and draws the ala towards the septum.

IV. MUSCLES OF THE MOUTH

Quadratus labii superioris.

Caninus.

Zygomaticus

Mentalis.

Quadratus labii inferioris.

Triangularis.

Buccinator.

Orbicularis oris.

Risorius.

The **Quadratus labii superioris** is a broad sheet, the origin of which extends from the side of the nose to the zygomatic bone. Its medial fibres form the *angular head*, which arises by a pointed extremity from the upper part of the frontal process of the maxilla, and passing obliquely downwards and lateralwards divides into two slips. One of these is inserted into the greater alar cartilage and skin of the nose; the other is prolonged into the lateral part of the upper lip, blending with the infraorbital head and with the **Orbicularis oris**. The intermediate portion or *infraorbital head* arises from the lower margin of the orbit immediately above the infraorbital foramen, some of its fibres being attached to the maxilla, others to the zygomatic bone. Its fibres converge, to be inserted into the muscular substance of the upper lip between the angular head and the **Caninus**. The lateral fibres form the *zygomatic head*, and are separated from the rest of the muscle by a narrow interval; they arise from the malar surface of the zygomatic bone immediately behind the zygomaticomaxillary suture and pass downwards and medialwards to the upper lip.

The **Caninus** (**Levator anguli oris**) arises from the canine fossa, immediately below the infraorbital foramen; its fibres are inserted into the angle of the mouth, intermingling with those of the **Zygomaticus**, **Triangularis**, and **Orbicularis oris**.

The **Zygomaticus** arises from the zygomatic bone, in front of the zygomaticotemporal suture, and descending obliquely with a medial inclination, is inserted into the angle of the mouth, where it blends with the fibres of the **Caninus**, **Orbicularis oris**, and **Triangularis**.

The **Mentalis** (**Levator menti**) is a conical fasciculus, situated at the side of the frenulum of the lower lip. It arises from the incisive fossa of the mandible, and descends to be inserted into the integument of the chin.

The **Quadratus labii inferioris** is a quadrilateral muscle. It arises from the oblique line of the mandible, between the symphysis and the mental foramen, and passes upwards and medialwards, to be inserted into the integument of the lower lip, its fibres blending with the **Orbicularis oris**, and with those of its fellow of the opposite side. At its origin it is continuous with the fibres of the **Platysma**. Much yellow fat is intermingled with the fibres of this muscle.

The **Triangularis** (**Depressor anguli oris**) arises from the oblique line of the mandible below and lateral to the **Quadratus labii inferioris**; its fibres converge and are inserted by a narrow fasciculus into the angle of the mouth. At its origin it is continuous with the **Platysma**, and at its insertion with the **Orbicularis oris** and **Risorius**; some of its fibres are directly continuous with

those of the Caninus, and others are occasionally found crossing from the muscle of one side to that of the other; these latter fibres constitute the *Transversus menti*.

The **Buccinator** (fig. 519) is a thin quadrilateral muscle, occupying the interval between the maxilla and the mandible at the side of the face. It arises from the outer surfaces of the alveolar processes of the maxilla and mandible, corresponding to the three molar teeth; and behind, from the anterior border of the pterygomandibular raphe which separates it from the Constrictor pharyngis superior. The fibres converge towards the angle of the mouth, where the central fibres intersect each other, those from below being continuous with the upper segment of the Orbicularis oris, and those from above with the lower segment; the highest and lowest fibres are continued forward into the corresponding lip without decussation.

Relations.—The Buccinator is covered by the buccopharyngeal fascia, and is in relation by its *superficial surface*, behind, with a large mass of fat, which separates it from the ramus of the mandible, the Masseter, and a small portion of the Temporalis; this fat has been named the *suctorial pad*, because it is supposed to assist in the act of sucking. In front the superficial surface of the Buccinator is in relation with the Zygomaticus, Risorius, Caninus, Triangularis, and the parotid duct which pierces it opposite the second molar tooth of the maxilla; the external maxillary artery and anterior facial vein cross it from below upwards; it is also crossed by branches of the facial and buccinator nerves. The *deep surface* is in relation with the buccal glands and mucous membrane of the mouth.

The *pterygomandibular raphe* is a tendinous band of the buccopharyngeal fascia, attached by one extremity to the hamulus of the medial pterygoid lamina, and by the other to the posterior end of the mylohyoid line of the mandible. Its *medial surface* is covered by the mucous membrane of the mouth. Its *lateral surface* is separated from the ramus of the mandible by a quantity of adipose tissue. Its *posterior border* gives attachment to the Constrictor pharyngis superior; its *anterior border* to part of the Buccinator (fig. 519).

The **Orbicularis oris** (figs. 517, 520) is not a simple sphincter muscle like the Orbicularis oculi; it consists of numerous strata of muscular fibres surrounding the orifice of the mouth but having different directions. It consists partly of fibres derived from the other facial muscles which are inserted into the lips, and partly of fibres proper to the lips. Of the former, a considerable number are derived from the Buccinator, and form the deeper stratum of the Orbicularis. Some of the Buccinator fibres—namely, those near the middle of the muscle—decussate at the angle of the mouth, those arising from the maxilla passing to the lower lip, and those from the mandible to the upper lip. The uppermost and lowermost fibres of the Buccinator pass across the lips from side to side without decussation. Superficial to this is a second stratum, formed

on either side by the Caninus and Triangularis, which cross each other at the angle of the mouth; the fibres from the Caninus pass to the lower lip, and those from the Triangularis to the upper lip, along which they run, to be inserted into the skin near the median line. In addition to these there are fibres from the Quadratus labii superioris, the Zygomaticus, and the Quadratus labii

FIG. 519.—Muscles of the pharynx and cheek.

inferioris; these intermingle with the transverse fibres described above, and have principally an oblique direction. The proper fibres of the lips are oblique, and pass from the deep surface of the skin to the mucous membrane, through the thickness of the lip. Finally there are fibres by which the muscle is connected with the maxillæ and the septum of the nose above and with the mandible below. In the upper lip these consist of two bands, lateral and medial, on either side of the middle line; the lateral band (*m. incisivus labii superioris*) arises from the alveolar border of the maxilla, opposite the lateral incisor tooth, and arching lateralwards is continuous with the other muscles at the angle of the mouth; the medial band (*m. nasolabialis*) connects the upper lip to the back of the septum of the nose. The interval between the two medial bands corresponds with the depression, called the *philtrum*, seen on the lip beneath the septum of the nose. The additional fibres for the lower lip constitute a slip (*m. incisivus labii inferioris*) on either side of the middle line; this arises from the mandible, laterally to the Mentalis, and intermingles with the other muscles at the angle of the mouth.

The **Risorius** arises from the parotideomasseteric fascia and is inserted into the skin at the angle of the mouth (fig. 517). It is a narrow bundle of fibres, broadest at its origin, but varies much in its size and form.

Nerves.—The muscles in this group are all supplied by the facial nerve.

Actions.—The *Quadratus labii superioris* raises the upper lip, and at the same time carries it a little forwards. Its angular head also acts as a dilatator of the

FIG. 520.—Scheme showing arrangement of fibres of *Orbicularis oris*.

nares; the infraorbital and zygomatic heads assist in forming the nasolabial furrow, which passes from the side of the nose to the upper lip and gives to the face an expression of sadness. When the whole muscle is in action it gives to the countenance an expression of contempt and disdain. The *Caninus* raises the angle of the mouth and assists the *Quadratus labii superioris* in producing the nasolabial furrow. The *Zygomaticus* draws the angle of the mouth backwards and upwards, as in laughing. The *Mentalis* raises and protrudes the lower lip, and at the same time wrinkles the skin of the chin, expressing doubt or disdain. The *Quadratus labii*

inferioris draws the lower lip directly downwards and a little lateralwards, as in the expression of irony. The *Triangularis* depresses the angle of the mouth, being the antagonist of the *Caninus* and *Zygomaticus*; acting with the *Caninus*, it will draw the angle of the mouth medialwards. The *Orbicularis oris* in its ordinary action effects the direct closure of the lips; by its deep, assisted by the oblique fibres, it closely applies the lips to the alveolar arches. The superficial part, consisting principally of the decussating fibres, brings the lips together and protrudes them. The *Buccinators* compress the cheeks, so that, during the process of mastication, the food is kept under the immediate pressure of the teeth. When the cheeks have been previously distended with air, the *Buccinator* muscles expel it from between the lips, as in blowing a trumpet; hence the name (*buccina*, a trumpet). The *Risorius* retracts the angle of the mouth, and produces an unpleasant grinning expression.

V. MUSCLES OF MASTICATION

Masseter.
Temporalis.

Pterygoideus externus.
Pterygoideus internus.

Covering the *Masseter*, and firmly connected with it, is a strong layer of fascia derived from the fascia colli and named the *parotideomasseteric fascia*. It is attached to the lower border of the zygomatic arch, and invests the parotid gland (p. 435).

The **Masseter** (fig. 517) is a quadrilateral muscle, consisting of two portions, superficial and deep. The *superficial portion*, the larger, arises by a thick aponeurosis from the zygomatic process of the maxilla, and from the anterior two-thirds of the lower border of the zygomatic arch; its fibres pass downwards and backwards, to be inserted into the angle and lower half of the lateral surface of the ramus of the mandible. The *deep portion* is much smaller and is partly concealed by the superficial portion; it arises from the posterior third of the lower border and from the whole of the medial surface of the zygomatic arch; its fibres pass downwards and forwards, to be inserted into the lateral surfaces of the coronoid process and the upper half of the ramus of the mandible.

Relations.—*Superficially* to the muscle are the integument, the Platysma, the Risorius, the Zygomaticus, and the parotid gland; the parotid duct, the branches of the facial nerve and the transverse facial vessels cross the muscle. The *deep surface* is in relation with the insertion of the Temporalis and the ramus of the mandible; a mass of fat separates it from the Buccinator muscle and nerve. The masseteric nerve and artery enter the muscle on its deep surface. The *posterior margin* is overlapped by the parotid gland; the *anterior* projects over the Buccinator and is crossed below by the anterior facial vein.

The **temporal fascia** covers the Temporalis. It is a strong, fibrous investment, covered, laterally, by the Auriculares anterior and superior, galea aponeurotica, and part of the Orbicularis oculi. The superficial temporal vessels and the auriculotemporal nerve cross it from below upwards. Above, it is a single

FIG. 521.—The Temporalis; the zygomatic arch and Masseter have been removed.

layer, attached to the entire extent of the superior temporal line; below, it consists of two layers, one of which is attached to the lateral, and the other to the medial border of the zygomatic arch. A small quantity of fat, the orbital branch of the superficial temporal artery, and the zygomaticotemporal branch of the maxillary nerve, are contained between these two layers. The deep surface of the fascia affords attachment to the superficial fibres of the Temporalis.

The **Temporalis** (fig. 521) is a fan-shaped muscle, situated at the side of the head. It arises from the whole of the temporal fossa (except that portion which is formed by the zygomatic bone) and from the deep surface of the temporal fascia. Its fibres converge as they descend, and end in a tendon which passes deep to the zygomatic arch and is inserted into the medial surface,

apex, and anterior border of the coronoid process, and the anterior border of the ramus of the mandible nearly as far forwards as the last molar tooth.

Relations.—*Superficially* to the muscle are the skin, the Auriculares anterior and superior, the temporal fascia, the superficial temporal vessels, the auriculotemporal nerve, the temporal branches of the facial nerve, the zygomaticotemporal nerve, the galea aponeurotica, the zygomatic arch, and the Masseter. The *deep surface* is in relation with the temporal fossa, the Pterygoideus externus and part of the Buccinator, the internal maxillary artery and its deep temporal branches, the deep temporal nerves, and the buccinator vessels and nerve. *Behind* the tendon of the muscle are the masseteric vessels and nerve. The *anterior border* is separated from the zygomatic bone by a mass of fat.

The **Pterygoideus externus** (fig. 522) is a short, thick, muscle, somewhat conical in form. It arises by two heads: an *upper* from the lower part of the lateral surface of the great wing of the sphenoid and from the infratemporal crest: and a *lower* from the lateral surface of the lateral pterygoid lamina.

FIG. 522.—The Pterygoidei; the zygomatic arch and a portion of the ramus of the mandible have been removed.

Its fibres pass horizontally backwards and lateralwards, to be inserted into a depression (pterygoid fovea) on the front of the neck of the condyle of the mandible, and into the anterior margin of the articular disc of the temporo-mandibular articulation.

Relations—Its *superficial surface* is in relation with the ramus of the mandible, the internal maxillary artery, which crosses it,* the tendon of the Temporalis, and the Masseter. Its *deep surface* rests against the upper part of the Pterygoideus internus, the sphenomandibular ligament, the middle meningeal artery, and the mandibular nerve; its *upper border* is in relation with the temporal and masseteric branches of the mandibular nerve; its *lower border* with the lingual and inferior alveolar nerves. The buccinator nerve and the internal maxillary artery pass between the heads of the muscle.

The **Pterygoideus internus** (fig. 522), a thick, quadrilateral muscle, arises from the medial surface of the lateral pterygoid lamina and the grooved surface of the pyramidal process of the palatine bone; it has a second slip of origin from the lateral surfaces of the pyramidal process of the palatine and tuberosity of the maxilla. Its fibres pass downwards, lateralwards, and backwards, and are inserted, by a strong tendinous lamina, into the lower and back part of the medial surfaces of the ramus and angle of the mandible, as high as the mandibular foramen.

* In many cases the artery lies deep to the muscle.

Relations.—The *lateral surface* of the muscle is, in relation with the ramus of the mandible, from which it is separated, at its upper part, by the Pterygoideus externus, the sphenomandibular ligament, the internal maxillary artery, the inferior alveolar vessels and nerve, the lingual nerve, and a process of the parotid gland. The *medial surface* is in relation with the Tensor veli palatini, and is separated from the Constrictor pharyngis superior by some areolar tissue.

Nerves.—The muscles of mastication are supplied by the mandibular nerve.

Actions.—The Temporalis, Masseter, and Pterygoideus internus raise the mandible against the maxillæ with great force. The Pterygoideus externus assists in opening the mouth by pulling forwards the condyle of the mandible and the articular disc, at the same time that the body of the mandible is depressed; but its main action is to protrude the mandible so that the inferior incisors are projected in front of the upper; in this action it is assisted by the Pterygoideus internus. The mandible is retracted by the posterior fibres of the Temporalis. If the Pterygoidei of one side act, the corresponding side of the mandible is drawn forward, while the opposite condyle remains comparatively fixed, and side-to-side movements, such as occur during the trituration of food, take place.

FASCIÆ AND MUSCLES OF THE ANTEROLATERAL REGION OF THE NECK

The anterolateral muscles of the neck may be arranged into the following groups:

- | | |
|--------------------------------------|--------------------------|
| I. Superficial and lateral cervical. | III. Anterior vertebral. |
| II. Supra- and infra-hyoid. | IV. Lateral vertebral. |

The **superficial fascia** of the neck is a thin lamina investing the Platysma, and is hardly demonstrable as a separate membrane.

The **fascia colli** (deep cervical fascia) (fig. 523) lies under cover of the Platysma, and invests the muscles of the neck; it also forms sheaths for the carotid vessels, and for the structures situated in front of the vertebral column.

The investing portion of the fascia is attached behind to the ligamentum nuchæ and to the spinous process of the seventh cervical vertebra. It forms a thin investment for the Trapezius, and from the anterior border of this muscle is continued forwards as a rather loose areolar layer, covering the posterior triangle of the neck, to the posterior border of the Sternocleidomastoideus, where it begins to assume the appearance of a fascial membrane. Along the hinder edge of the Sternocleidomastoideus it divides to enclose the muscle, and at the anterior margin again forms a single lamella, which covers the anterior triangle of the neck, and reaches forwards to the middle line, where it is continuous with the corresponding part from the opposite side of the neck. In the middle line of the neck it is fixed to the symphysis menti and the body of the hyoid bone.

Above, the fascia is attached to the superior nuchal line of the occipital bone, to the mastoid process of the temporal bone, and to the whole length of the inferior border of the body of the mandible. Opposite the angle of the mandible it is very strong, and binds the anterior edge of the Sternocleidomastoideus firmly to that bone. Between the mandible and the mastoid process it ensheathes the parotid gland—the layer which covers the gland extends upwards under the name of the *parotidomasseteric fascia* and is fixed to the zygomatic arch. From the part which passes under the parotid gland a strong band ascends to the styloid process, forming the *stylomandibular ligament* (p. 347). Two other bands may be defined: the *sphenomandibular* (p. 347) and the *pterygospinous ligaments*. The *pterygospinous ligament* stretches from the upper part of the posterior border of the lateral pterygoid lamina to the spinous process of the sphenoid. It occasionally ossifies, and in such cases, between its upper border and the base of the skull, a foramen is formed which transmits the branches of the mandibular nerve to the muscles of mastication.

Below, the fascia is attached to the acromion, the clavicle, and the manubrium sterni. Some little distance above the last, it splits into a superficial and a deep layer. The former is attached to the anterior border of the manubrium

the latter to its posterior border and to the interclavicular ligament. Between these two layers is a slit-like interval, the *suprasternal space*, or *space of Burns*; it contains a small quantity of areolar tissue, the lower portions of the anterior jugular veins and their transverse connecting branch, the sternal heads of the Sternocleidomastoidei, and sometimes a lymph-gland.

The fascia which lines the deep surface of the Sternocleidomastoideus gives off the following processes: (1) A process envelops the tendon of the Omo-

FIG. 523.—Section of the neck at about the level of the sixth cervical vertebra, showing the arrangement of the fascia colli.

hyoideus, and binds it down to the sternum and first costal cartilage. (2) The *carotid sheath* encloses the carotid artery, internal jugular vein, and vagus nerve. (3) The *prevertebral fascia* extends medialwards behind the carotid vessels, where it assists in forming their sheath, and passes in front of the prevertebral muscles. It forms the posterior wall of a fibrous compartment which contains the larynx and trachea, the thyroid gland, and the pharynx and oesophagus. The prevertebral fascia is fixed above to the base of the skull, and below is continued into the thorax in front of the Longus colli muscles. Parallel to the carotid sheath and along its medial aspect the prevertebral fascia gives off a thin lamina, the *buccopharyngeal fascia*, which closely invests the Constrictor

muscles of the pharynx, and is continued forward from the Constrictor pharyngis superior on to the Buccinator. It is attached to the prevertebral layer by loose connective tissue only, and thus an easily distended space, the *retropharyngeal space*, is found between them. This space is limited above by the base of the skull; below it extends behind the œsophagus into the posterior mediastinal cavity of the thorax. The prevertebral fascia is prolonged downwards and lateralwards behind the carotid vessels and in front of the Scaleri, and forms a sheath for the brachial nerves and subclavian vessels in the posterior triangle of the neck; it is continued under the clavicle as the axillary sheath and is attached to the deep surface of the coracoclavicular fascia. Immediately above and behind the clavicle an areolar space exists between the investing layer and the sheath of the subclavian vessels, and in this space are found the lower part of the external jugular vein, the supraclavicular nerves, the transverse scapular and transverse cervical vessels, and the inferior belly of the Omohyoideus muscle. This space is limited below by the fusion of the coracoclavicular fascia with the anterior wall of the axillary sheath. (4) The *pretracheal fascia* extends medialwards in front of the carotid vessels, and assists in forming the carotid sheath. It is continued behind the infrahyoid muscles, and, after enveloping the thyroid gland, is prolonged in front of the trachea to meet the corresponding layer of the opposite side. Above, it is fixed to the hyoid bone, while below, it is carried downwards in front of the trachea and large vessels at the root of the neck, and ultimately blends with the fibrous pericardium. This layer is fused on either side with the prevertebral fascia, and with it completes the compartment containing the larynx and trachea, the thyroid gland, and the pharynx and œsophagus.*

Applied Anatomy.—The fascia colli (deep cervical fascia) is of considerable importance from a surgical point of view. The investing layer opposes the extension of abscesses towards the surface, and pus forming beneath it has a tendency to extend lateralwards. If the pus be contained in the anterior triangle, it may find its way into the anterior mediastinal cavity, in front of the pretracheal layer of fascia; but owing to the thinness of the fascia in this situation it more frequently finds its way to the surface and points above the sternum. Pus forming under cover of the pretracheal layer would in all probability find its way into the posterior mediastinal cavity. Pus forming behind the prevertebral layer, in cases, for instance, of caries of the bodies of the cervical vertebrae, may extend towards the lateral part of the neck and point in the posterior triangle, or may perforate this layer of fascia and the buccopharyngeal fascia and point into the pharynx (retropharyngeal abscess).

In cases of cut throat, when the wound involves only the investing layer the injury is usually trivial, the special danger being injury to the external jugular vein, and the special complication, diffuse cellulitis. But where the second of the two layers is opened up, important structures may be injured, and serious results follow.

The sternal head of origin of the Sternocleidomastoideus is contained in the supra-sternal space, so that this space is opened in division of this tendon. The lower part of the anterior jugular vein is also contained in the same space.

I. SUPERFICIAL AND LATERAL CERVICAL MUSCLES

Platysma. Trapezius. Sternocleidomastoideus.

The **Platysma** (fig. 517) is a broad sheet arising from the fascia covering the upper parts of the Pectoralis major and Deltoides; its fibres cross the clavicle, and proceed obliquely upwards and medialwards along the side of the neck. The anterior fibres interlace, below and behind the symphysis menti, with the fibres of the muscle of the opposite side; the posterior fibres cross the mandible, some being inserted into the bone below the oblique line, others into the skin and subcutaneous tissue of the lower part of the face, many of these fibres blending with the muscles about the angle and lower part of the mouth. Sometimes fibres can be traced to the Zygomaticus, or to the margin of the Orbicularis oculi. Beneath the Platysma, the external jugular vein descends from the angle of the mandible to the clavicle.

* F. G. Parsons (*Journal of Anatomy and Physiology*, vol. xlv.) regards the carotid sheath and the fascial planes in the neck as structures which are artificially produced by dissection.

Actions.—When the entire *Platysma* is in action it produces a wrinkling of the surface of the skin of the neck in an oblique direction. Its anterior portion, the thickest part of the muscle, depresses the mandible; it also serves to draw down the lower lip and angle of the mouth in the expression of melancholy.

Nerve.—The *Platysma* is supplied by the cervical branch of the facial nerve.

The *Trapezius* is described on p. 478.

The *Sternocleidomastoideus* (fig 524) passes obliquely across the side of the neck. It is thick and narrow at its central part, but broader and thinner at either end. It arises by two heads. The *medial* or *sternal* head is a rounded tendinous fasciculus, which arises from the upper part of the anterior surface of the manubrium sterni, and is directed upwards, lateralwards, and backwards. The *lateral* or *clavicular* head, composed of fleshy and aponeurotic fibres, arises

FIG. 524.—Muscles of the neck. Lateral view.

from the superior border and anterior surface of the medial third of the clavicle, and is directed almost vertically upwards. The two heads are separated from one another at their origins by a triangular interval, but gradually blend, below the middle of the neck, into a thick, rounded belly. The muscle is inserted, by a strong tendon, into the lateral surface of the mastoid process, from its apex to its superior border, and by a thin aponeurosis into the lateral half of the superior nuchal line of the occipital bone.

The *Sternocleidomastoideus* varies much in its extent of origin from the clavicle: in some cases the clavicular may be as narrow as the sternal head; in others, as much as 7.5 cm. in breadth. When the clavicular origin is broad, it is occasionally subdivided into several slips. More rarely, the adjoining margins of the *Sternocleidomastoideus* and *Trapezius* are in contact.

This muscle divides the quadrilateral area of the side of the neck into two triangles, an anterior and a posterior. The boundaries of the *anterior triangle* are, in front, the median line of the neck; above, the lower border of the body of the mandible, and an imaginary line drawn from the angle of the mandible to the *Sternocleidomastoideus*; behind, the anterior border of the *Sternocleidomastoideus*.

The apex of the triangle is at the upper border of the sternum. The boundaries of the *posterior triangle* are, in front, the posterior border of the Sternocleidomastoideus; below, the middle third of the clavicle; behind, the anterior margin of the Trapezius. The apex corresponds with the meeting of the Sternocleidomastoideus and Trapezius on the occipital bone.

Relations.—*Superficially* to the muscle are the integument and Platysma; it is separated from the Platysma by the external jugular vein, the great auricular and cervical cutaneous nerves, and the investing layer of the deep cervical fascia. The *deep surface* is in relation with the sternoclavicular articulation, the process of the deep cervical fascia which binds the inferior belly of the Omohyoideus to the sternum and clavicle, the Sternohyoideus, Sternothyroideus, Omohyoideus, posterior belly of the Digastricus, Levator scapulæ, Splenius and Scaleri muscles, the common carotid artery, the internal and anterior jugular veins, the origins of the internal and external carotid arteries, the occipital, subclavian, transverse cervical, and transverse scapular arteries and veins, the phrenic, vagus, hypoglossal, descendens and communicantes hypoglossi nerves, the accessory nerve which pierces its upper third, the cervical plexus, the upper part of the brachial plexus, parts of the thyroid and parotid glands and their vessels, and the deep cervical lymph-glands.

Nerves.—The Sternocleidomastoideus is supplied by the accessory nerve and branches from the anterior divisions of the second and third cervical nerves.

Actions.—When one Sternocleidomastoideus acts, it draws the head towards the shoulder of the same side, assisted by the Splenius and the Obliquus capitis inferior of the opposite side; it also rotates the head so as to carry the face towards the opposite side. Acting together from their sternoclavicular attachments the two muscles will flex the cervical part of the vertebral column; if the head be fixed they will assist in elevating the thorax in forced inspiration.

Applied Anatomy.—The surgical anatomy of the Sternocleidomastoideus is of importance in connexion with the deformity known as *wry-neck*, which is due to a contracted condition of this muscle. The wry-neck may be temporary, as the result of direct irritation of the muscle or of the nerves supplying it, and may occur in acute glandular enlargement, cellulitis of the neck, myositis of the muscle, or cervical caries. It may, however, be permanent, and is then most often due to injury to the muscle during birth, especially in breech presentations, rupture of the fibres and subsequent cicatricial contraction taking place. In these cases, division of the muscle is often necessary to effect a cure, and this may be done either subcutaneously or through an open wound. The open method is, however, much to be preferred, as being the more effectual and the less dangerous, if precautions are taken to keep the wound aseptic. The tendons of origin are freely exposed by a horizontal incision across the root of the neck and carefully divided; any tense bands of fascia which exist should also be divided. The wound is now sutured and dressed, and the head fixed in as straight a position as possible.

There is also a condition coming on in adult life (spasmodic torticollis), which is a very distressing form of functional nervous disease. It begins with tonic or clonic spasm of one Sternocleidomastoideus, which is soon followed by spasm of the Trapezius, particularly its clavicular portion. The Splenius of the opposite side, the Scaleri, Semispinales capitis, and Longissimi capitis may all become involved in turn, with secondary contracture of the deep cervical fascia. Operation in these cases often fails to give satisfactory results. Tenotomy of the affected muscles or section of the nerves supplying them may afford temporary relief, but the spasm often returns when the cut nerves or muscles rejoin.

II. SUPRA- AND INFRA-HYOID MUSCLES (figs. 524, 525)

The suprahyoid muscles are :

Digastricus.
Stylohyoideus.

Mylohyoideus.
Geniohyoideus.

The **Digastricus** consists of two fleshy bellies united by an intermediate rounded tendon. It lies below the body of the mandible, and extends, in a curved form, from the mastoid process to the chin. The *posterior belly*, longer than the anterior, arises from the mastoid notch (digastric fossa) of the temporal bone and passes downwards and forwards. The *anterior belly* arises from a depression on the inner side of the lower border of the body of the mandible, close to the middle line, and passes downwards and backwards. The two bellies

end in an intermediate tendon which perforates the Stylohyoideus muscle, and is held in connexion with the side of the body and the greater cornu of the hyoid bone by a fibrous loop, which is sometimes lined by a mucous sheath. An aponeurotic layer is given off from the tendon of the Digastricus on either side of the neck, to be attached to the body and greater cornua of the hyoid bone; this is termed the *suprahyoid aponeurosis*.

Relations.—Its *superficial surface* is in relation with the Platysma, Sternocleidomastoideus, part of the Splenius, Longissimus capitis, mastoid process, Stylohyoideus, and the parotid gland. The *deep surface* of the anterior belly lies on the Mylohyoideus: that of the posterior belly on the Styloglossus, Stylopharyngeus, and Hyoglossus, the external carotid artery and its occipital, lingual, external maxillary, and ascending pharyngeal branches, the internal carotid artery, internal jugular vein, and hypoglossal nerve.

FIG. 525.—Muscles of the neck. Anterior view.

The Digastricus divides the upper part of the anterior triangle of the neck into three triangles: (1) the *submaxillary triangle*, bounded above by the lower border of the mandible and a line drawn from its angle to the Sternocleidomastoideus, below by the posterior belly of the Digastricus and the Stylohyoideus, in front by the anterior belly of the Digastricus; (2) the *carotid triangle*, bounded above by the posterior belly of the Digastricus and Stylohyoideus, behind by the Sternocleidomastoideus, below by the Omohyoideus; (3) the *suprahyoid or submental triangle*, bounded laterally by the anterior belly of the Digastricus, medially by the middle line of the neck from the hyoid bone to the symphysis menti, and inferiorly by the body of the hyoid bone.

The **Stylohyoideus** is a slender muscle, lying in front of, and above, the posterior belly of the Digastricus. It arises from the posterior and lateral surfaces of the styloid process, near the base; and, passing downwards and forwards, is inserted into the body of the hyoid bone, at its junction with the greater cornu, and just above the Omohyoideus. It is perforated, near its insertion, by the tendon of the Digastricus.

The *stylohyoid ligament*.—In connexion with the Stylohyoideus muscle a ligamentous band, the *stylohyoid ligament*, may be described. It is a fibrous cord, which is attached to the tip of the styloid process of the temporal bone and the lesser cornu of the hyoid bone. It frequently contains a little cartilage in its centre, is often partially ossified, and in many animals forms a distinct bone, the *epihyal*.

The *Mylohyoideus*, flat and triangular, is situated immediately above the anterior belly of the Digastricus, and forms, with its fellow of the opposite side, a muscular floor for the cavity of the mouth. It arises from the whole length of the mylohyoid line of the mandible. The posterior fibres pass medialwards and slightly downwards, to be inserted into the front of the body of the hyoid bone near its lower border. The middle and anterior fibres are inserted into a median fibrous raphe extending from the symphysis menti to the hyoid bone, where they join at an angle with the fibres of the opposite muscle. This median raphe is sometimes wanting; the fibres of the two muscles are then continuous.

Relations.—Its *superficial or inferior surface* is in relation with the Platysma, the anterior belly of the Digastricus, the suprahyoid aponeurosis, the superficial part of the submaxillary gland, the external maxillary and submental vessels, and the mylohyoid vessels and nerve. Its *deep or superior surface* is in relation with the Geniohyoideus, part of the Hyoglossus, and the Styloglossus, the hypoglossal and lingual nerves, the submaxillary ganglion, the sublingual gland, the deep portion of the submaxillary gland and the submaxillary duct, the lingual and sublingual vessels, and the buccal mucous membrane.

The *Geniohyoideus* is a narrow muscle, situated above the medial part of the Mylohyoideus. It arises from the inferior mental spine on the back of the symphysis menti, and runs backwards and slightly downwards, to be inserted into the anterior surface of the body of the hyoid bone; it is in contact with its fellow of the opposite side.

Nerves.—The Mylohyoideus and anterior belly of the Digastricus are supplied by the mylohyoid branch of the inferior alveolar nerve; the Stylohyoideus and posterior belly of the Digastricus, by the facial; the Geniohyoideus, by the first cervical nerve through the hypoglossal.

Actions.—These muscles perform two very important actions. During the act of deglutition they raise the hyoid bone, and with it the base of the tongue; when the hyoid bone is fixed by its depressors and those of the larynx, they depress the mandible. During the first act of deglutition, when the mass of food is being driven from the mouth into the pharynx, the hyoid bone (and with it the tongue) is carried upwards and forwards by the anterior bellies of the Digastrici, the Mylohyoidei, and Geniohyoidei. In the second act, when the mass is passing through the pharynx, the direct elevation of the hyoid bone takes place by the combined action of all the muscles; and after the food has passed, the hyoid bone is carried upwards and backwards by the posterior bellies of the Digastrici and the Stylohyoidei, which assist in preventing the return of the food into the mouth.

The infrahyoid muscles are :

Sternohyoideus.
Sternothyreoideus.

Thyreohyoideus.
Omohyoideus.

The *Sternohyoideus*, a thin, narrow muscle, arises from the posterior surface of the medial end of the clavicle, the capsule of the sternoclavicular joint, and the upper and posterior part of the manubrium sterni. Passing upwards and medialwards, it is inserted, by short tendinous fibres, into the lower border of the body of the hyoid bone. It sometimes presents, immediately above its origin, a transverse tendinous inscription. Below, the Sternohyoideus is separated from its fellow by a considerable interval; but the two muscles come into contact with one another in the middle of their course, and, from this upwards, lie side by side.

The *Sternothyreoideus* is shorter and wider than the preceding muscle, and lies under cover of it. It arises from the posterior surface of the manubrium sterni, below the origin of the Sternohyoideus, and from the edge of the cartilage of the first, and sometimes that of the second, rib; it is inserted

into the oblique line on the lamina of the thyroid cartilage. This muscle is in close contact with its fellow at the lower part of the neck, but diverges somewhat as it ascends; it is occasionally traversed by a transverse or oblique tendinous inscription.

The **Thyreohyoideus**, a small, quadrilateral muscle, may be looked upon as an upward continuation of the Sternothyroideus. It arises from the oblique line on the lamina of the thyroid cartilage, and is inserted into the lower border of the greater cornu of the hyoid bone.

The **Omohyoideus** consists of two fleshy bellies united by a central tendon. It arises from the upper border of the scapula, and occasionally from the superior transverse ligament which crosses the scapular notch, its extent of attachment to the scapula varying from a few millimetres to 2.5 cm. From this origin, the *inferior belly* forms a flat, narrow fasciculus, which inclines forwards and slightly upwards across the lower part of the neck, being bound to the clavicle by a fibrous expansion; it then passes behind the Sternocleidomastoideus, becomes tendinous and changes its direction, forming an obtuse angle. It ends in the *superior belly*, which passes almost vertically upwards close to the lateral border of the Sternohyoideus, and is inserted into the lower border of the body of the hyoid bone, lateral to the insertion of the Sternohyoideus. The central tendon of this muscle varies in length and form, and is held in position by a process of the deep cervical fascia, which ensheathes it and is prolonged down to be attached to the clavicle and first rib; it is by this means that the angular form of the muscle is maintained.

The inferior belly of the Omohyoideus divides the posterior triangle of the neck into an upper or *occipital* and a lower or *subclavian* triangle, while its superior belly divides the anterior triangle into an upper or *carotid* and a lower or *muscular* triangle.

Nerves.—The Thyreohyoideus is supplied by a branch from the hypoglossal nerve; the superior belly of the Omohyoideus by the descendens hypoglossi; the Sternohyoideus, Sternothyroideus, and inferior belly of the Omohyoideus are supplied by branches from a loop (ansa hypoglossi) between the descendens hypoglossi and the communicantes cervicales.

Actions.—These muscles depress the larynx and hyoid bone, after they have been drawn up with the pharynx in the act of deglutition. The Omohyoidei not only depress the hyoid bone, but carry it backwards and to one or the other side. They are concerned also in prolonged inspiratory efforts; for by rendering the lower part of the cervical fascia tense they lessen the inward suction of the soft parts, which would otherwise compress the great vessels and the apices of the lungs. The Thyreohyoideus may act as an elevator of the thyroid cartilage, drawing the cartilage up behind the hyoid bone. The Sternothyroideus acts as a depressor of the thyroid cartilage.

III. ANTERIOR VERTEBRAL MUSCLES (fig. 526)

Longus colli.
Longus capitis.

Rectus capitis anterior.
Rectus capitis lateralis.

The **Longus colli** is situated on the anterior surface of the vertebral column, between the atlas and the third thoracic vertebra. It is divisible into three portions, a superior oblique, an inferior oblique, and a vertical; its origin and insertion consist of tendinous slips. The *superior oblique portion* arises from the anterior tubercles of the transverse processes of the third, fourth, and fifth cervical vertebrae; it is directed upwards and medialwards, and is inserted by a narrow tendon into the tubercle on the anterior arch of the atlas. The *inferior oblique portion*, the smallest part of the muscle, arises from the front of the bodies of the first two or three thoracic vertebrae; it runs upwards and lateralwards, and is inserted into the anterior tubercles of the transverse processes of the fifth and sixth cervical vertebrae. The *vertical portion* arises from the front of the bodies of the upper three thoracic and lower three cervical vertebrae, and is inserted into the front of the bodies of the second, third, and fourth cervical vertebrae.

The **Longus capitis** (*Rectus capitis anticus major*), broad and thick above, narrow below, arises by tendinous slips, from the anterior tubercles of the

transverse processes of the third, fourth, fifth, and sixth cervical vertebræ, and is inserted into the inferior surface of the basilar part of the occipital bone.

The **Rectus capitis anterior** (*Rectus capitis anticus minor*) is a short, flat muscle, situated behind the upper part of the *Longus capitis*. It arises from the anterior surface of the lateral mass of the atlas, and from the root of its transverse process, and is inserted into the inferior surface of the basilar part of the occipital bone in front of the occipital condyle.

FIG. 526.—The anterior and lateral vertebral muscles.

The **Rectus capitis lateralis**, a short, flat muscle, arises from the upper surface of the transverse process of the atlas, and is inserted into the under surface of the jugular process of the occipital bone.

Nerves.—These muscles receive their nerve-supply from the anterior divisions of the cervical nerves; the *Rectus capitis anterior* and the *Rectus capitis lateralis* from the loop between the first and second cervical; the *Longus capitis*, by branches from the first, second, and third cervical; the *Longus colli*, by branches from the second to the seventh cervical inclusive.

Actions.—The *Longus capitis* and *Rectus capitis anterior* are the direct antagonists of the muscles at the back of the neck, and serve to restore the head to its natural position after it has been drawn backwards. These muscles also flex the head, and, from their obliquity, rotate it, so as to turn the face to one or the other side. The *Rectus lateralis*, acting on one side, bends the head laterally. The *Longus colli* flexes and slightly rotates the cervical portion of the vertebral column.

IV. LATERAL VERTEBRAL MUSCLES (fig. 526)

Scalenus anterior.

Scalenus medius.

Scalenus posterior.

The **Scalenus anterior** lies deeply at the side of the neck, behind the Sternocleidomastoideus. It arises from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ, and descending, almost vertically, is inserted by a narrow, flat tendon into the scalene tubercle on the inner border of the first rib, and into the ridge on the upper surface of the rib in front of the subclavian groove.

Relations.—In front of it are the clavicle, the Subclavius, Sternocleidomastoideus, and Omohyoideus muscles, the transverse cervical, transverse scapular and ascending cervical arteries, the subclavian vein, and the phrenic nerve. Its *posterior surface* is in relation with the cords of the brachial plexus, the subclavian artery, and the pleura, which separate it from the Scalenus medius. Below, it is separated from the Longus colli by the vertebral artery, and above, from the Longus capitis by the ascending cervical branch of the inferior thyroid artery.

The **Scalenus medius**, the largest and longest of the three Scaleni, arises from the posterior tubercles of the transverse processes of the lower six cervical vertebræ, and descending along the side of the vertebral column, is inserted by a broad attachment into the upper surface of the first rib, between the tubercle and the subclavian groove.

Relations.—Its *anterior surface* is in relation with the Sternocleidomastoideus; it is crossed by the clavicle and the Omohyoideus; the subclavian artery and the cervical nerves separate it from the Scalenus anterior. *Lateral* to it are the Levator scapulæ and the Scalenus posterior. The long thoracic nerve is formed in the substance of the muscle and emerges from it; the dorsal scapular nerve pierces it.

The **Scalenus posterior**, the smallest and most deeply seated of the three Scaleni, arises from the posterior tubercles of the transverse processes of the lower two or three cervical vertebræ, and is inserted by a thin tendon into the outer surface of the second rib, behind the attachment of the Serratus anterior. It is occasionally blended with the Scalenus medius.

Nerves.—The Scaleni are supplied by branches from the second to the seventh cervical nerves.

Actions.—When the Scaleni act from above, they elevate the first and second ribs, and are, therefore, inspiratory muscles. Acting from below, they bend the vertebral column to one or other side; if the muscles of both sides act, the vertebral column is lightly flexed.

FASCIÆ AND MUSCLES OF THE TRUNK

The muscles of the trunk may be arranged in six groups:

- | | |
|------------------------------|------------------------------|
| I. Deep muscles of the back. | IV. Muscles of the abdomen. |
| II. Suboccipital muscles. | V. Muscles of the pelvis. |
| III. Muscles of the thorax. | VI. Muscles of the perinæum. |

I. DEEP MUSCLES OF THE BACK (fig. 528)

The deep or intrinsic muscles of the back consist of a complex group of muscles extending from the pelvis to the skull. They are:

Splenius capitis.
Splenius cervicis.
Sacrospinalis.
Semispinalis.

Multifidus.
Rotatores.
Interspinales.
Intertransversarii.

The **lumbodorsal fascia** covers the deep muscles of the back of the trunk. Above, it passes in front of the Serratus posterior superior and is continuous with the *nuchal fascia*, a similar investing layer on the back of the neck.

In the thoracic region the lumbodorsal fascia is a thin fibrous lamina covering the extensor muscles of the vertebral column and separating them from the muscles connecting the vertebral column to the upper extremity. It contains both longitudinal and transverse fibres, and is attached, *medially*, to the spinous processes of the thoracic vertebræ; *laterally*, to the angles of the ribs.

In the lumbar region the lumbodorsal fascia (lumbar aponeurosis) is in two layers, anterior and posterior (fig. 527). The posterior layer is attached to the spinous processes of the lumbar and sacral vertebræ and to the supraspinal ligament; the anterior is attached, *medially*, to the tips of the transverse processes of the lumbar vertebræ, and to the intertransverse ligaments, *below*, to the iliolumbar ligament, and *above*, to the lumbocostal ligament (p. 360). The two layers unite at the lateral margin of the Sacrospinalis, to form the tendon of origin of the Transversus abdominis.

The **Splenius capitis** (fig. 547) arises from the lower half of the ligamentum nuchæ, from the spinous process of the seventh cervical vertebra, and from the spinous processes of the upper three or four thoracic vertebræ. The fibres of the muscle are directed upwards and lateralwards and are inserted, under cover of the Sternocleidomastoideus, into the mastoid process of the temporal

FIG. 527.—Diagram of a transverse section of the posterior abdominal wall, to show the disposition of the lumbodorsal fascia.

bone, and into the rough surface on the occipital bone just below the lateral third of the superior nuchal line.

The **Splenius cervicis** (fig. 547) arises from the spinous processes of the third to the sixth thoracic vertebræ: it is inserted into the posterior tubercles of the transverse processes of the upper two or three cervical vertebræ.

Nerves.—The Splenii are supplied by the lateral branches of the posterior divisions of the middle and lower cervical nerves.

Actions.—The Splenii of the two sides, acting together, draw the head directly backwards, assisting the Trapezius and Semispinalis capitis; acting separately, they draw the head to one side, and slightly rotate it, turning the face to the same side. They also assist in supporting the head in the erect position.

The **Sacrospinalis** (fig. 528), and its prolongations in the thoracic and cervical regions, lie in the groove on the side of the vertebral column. They are covered in the lumbar and thoracic regions by the lumbodorsal fascia, and in the cervical region by the nuchal fascia. They form a large muscular and tendinous mass which varies in size and structure at different parts of the vertebral column. In the sacral region it is narrow and pointed, and at its origin chiefly tendinous in structure. In the lumbar region it is larger, and forms a thick fleshy mass which, on being followed upwards, is subdivided into three columns; these gradually diminish in size as they ascend to be inserted into the vertebræ and ribs.

The Sacrospinalis arises from the anterior surface of a broad and thick tendon, which is attached to the middle sacral crest, to the spinous processes of the lumbar and the eleventh and twelfth thoracic vertebræ, to the supraspinal ligament, to the posterior part of the inner lip of the iliac crest and to the lateral crest of the sacrum, where it blends with the sacrotuberous and posterior sacro-iliac ligaments; some of its fibres are continuous with the

FIG. 528.—Deep muscles of the Back.

fibres of origin of the *Glutæus maximus*. The muscular fibres form a large fleshy mass which splits in the upper lumbar region into three columns, viz. a lateral, the *Iliocostalis*, an intermediate, the *Longissimus*, and a medial, the *Spinalis*. Each of these consists, from below upwards, of three parts, as follows :

<i>Lateral Column.</i>	<i>Intermediate Column.</i>	<i>Medial Column.</i>
<i>Iliocostalis.</i>	<i>Longissimus.</i>	<i>Spinalis.</i>
(a) <i>I. lumborum.</i>	(a) <i>L. dorsi.</i>	(a) <i>S. dorsi.</i>
(b) <i>I. dorsi.</i>	(b) <i>L. cervicis.</i>	(b) <i>S. cervicis.</i>
(c) <i>I. cervicis.</i>	(c) <i>L. capitis.</i>	(c) <i>S. capitis.</i>

The *Iliocostalis lumborum* is inserted, by flattened tendons, into the inferior borders of the angles of the lower six or seven ribs.

The *Iliocostalis dorsi* (*Musculus accessorius*) arises from the upper borders of the angles of the lower six ribs medially to the tendons of insertion of the *Iliocostalis lumborum*; it is inserted into the upper borders of the angles of the upper six ribs and into the back of the transverse process of the seventh cervical vertebra.

The *Iliocostalis cervicis* (*Cervicalis ascendens*) arises from the angles of the third, fourth, fifth, and sixth ribs, and is inserted into the posterior tubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebrae.

The *Longissimus dorsi* is the intermediate and largest of the continuations of the *Sacrospinalis*. In the lumbar region, where it is as yet blended with the *Iliocostalis lumborum*, some of its fibres are attached to the whole length of the posterior surfaces of the transverse processes and the accessory processes of the lumbar vertebrae, and to the anterior layer of the lumbodorsal fascia. In the thoracic region it is inserted, by rounded tendons, into the tips of the transverse processes of all the thoracic vertebrae, and by fleshy processes into the lower nine or ten ribs between their tubercles and angles.

The *Longissimus cervicis* (*Transversarius cervicis*), situated medially to the *Longissimus dorsi*, arises by long thin tendons from the summits of the transverse processes of the upper four or five thoracic vertebrae, and is inserted by similar tendons into the posterior tubercles of the transverse processes of the cervical vertebrae from the second to the sixth inclusive.

The *Longissimus capitis* (*Trachelomastoides*) lies between the *Longissimus cervicis* and the *Semispinalis capitis*. It arises by tendons from the transverse processes of the upper four or five thoracic vertebrae, and the articular processes of the lower three or four cervical vertebrae, and is inserted into the posterior margin of the mastoid process, beneath the *Splenius capitis* and *Sternocleidomastoideus*. It is usually crossed by a tendinous inscription near its insertion.

The *Spinalis dorsi*, the medial continuation of the *Sacrospinalis*, is scarcely separable as a distinct muscle. It is situated at the medial side of the *Longissimus dorsi*, and is intimately blended with it; it arises by three or four tendons from the spinous processes of the first lumbar and the last two thoracic vertebrae: these, uniting, form a small muscle which is inserted by separate tendons into the spinous processes of the upper thoracic vertebrae, the number varying from four to eight. It is intimately united with the *Semispinalis dorsi*, situated beneath it.

The *Spinalis cervicis* is an inconstant muscle, which arises from the lower part of the ligamentum nuchae, the spinous process of the seventh cervical, and sometimes from the spinous processes of the first and second thoracic vertebrae, and is inserted into the spinous process of the epistropheus, and occasionally into the spinous processes of the two vertebrae below it.

The *Spinalis capitis* is usually inseparably connected with the *Semispinalis capitis* (p. 448).

The *Semispinalis dorsi* consists of thin, fleshy fasciculi, interposed between tendons of considerable length. It arises by a series of small tendons from the transverse processes of the sixth to the tenth thoracic vertebrae, and is inserted, by tendons, into the spinous processes of the upper four thoracic and lower two cervical vertebrae.

The *Semispinalis cervicis*, thicker than the preceding, arises by a series of tendinous and fleshy fibres from the transverse processes of the upper five or

six thoracic vertebræ, and is inserted into the cervical spinous processes; from the epistropheus to the fifth inclusive. The fasciculus connected with the epistropheus is the largest, and is chiefly muscular in structure.

The **Semispinalis capitis** (Complexus) is situated at the back part of the neck, beneath the Splenius, and medial to the Longissimi cervicis and capitis. It arises by a series of tendons from the tips of the transverse processes of the upper six or seven thoracic and the seventh cervical vertebræ, and from the articular processes of the fourth, fifth, and sixth cervical vertebræ. The tendons are succeeded by a broad muscle which passes upwards and is inserted between the superior and inferior nuchal lines of the occipital bone. The medial part, usually more or less distinct from the remainder of the muscle, is termed the *Spinalis capitis*: it is also named the *Biventer cervicis* since it is traversed by an imperfect tendinous inscription.

The **Multifidus** consists of a number of fleshy and tendinous fasciculi, which fill the groove on the side of the spinous processes of the vertebræ, from the sacrum to the epistropheus. In the sacral region, the fasciculi arise from the back of the sacrum, as low as the fourth sacral foramen, from the aponeurosis of origin of the Sacrospinalis, from the medial surface of the posterior superior iliac spine, and from the posterior sacro-iliac ligaments; in the lumbar region, from all the mamillary processes; in the thoracic region, from all the transverse processes; and in the cervical region, from the articular processes of the lower four vertebræ. Each fasciculus passes obliquely upwards and medialwards and is inserted into the whole length of the spinous process of one of the vertebræ above. The fasciculi vary in length: the most superficial pass from one vertebra to the third or fourth above; those next in order run from one vertebra to the second or third above; while the deepest connect contiguous vertebræ.

The **Rotatores** lie beneath the Multifidus and are found only in the thoracic region; they are eleven in number on either side and are small and somewhat quadrilateral in form. Each arises from the upper and posterior part of the transverse process, and is inserted into the lower border and lateral surface of the lamina of the vertebra above, the fibres extending as far as the root of the spinous process. The first is found between the first and second thoracic vertebræ; the last, between the eleventh and twelfth. Sometimes the number of these muscles is diminished by the absence of one or more from the upper or lower end of the series.

The **Interspinales** are short muscular fasciculi, placed in pairs between the spinous processes of the contiguous vertebræ, one on either side of the interspinal ligament. In the *cervical region* they are most distinct, and consist of six pairs, the first being situated between the epistropheus and third vertebra, and the last between the seventh cervical and the first thoracic. They are small narrow bundles, attached, above and below, to the apices of the spinous processes. In the *thoracic region* they are found between the first and second vertebræ, and sometimes between the second and third, and between the eleventh and twelfth. In the *lumbar region* there are four pairs in the intervals between the five lumbar vertebræ. There is also occasionally one between the last thoracic and first lumbar, and one between the fifth lumbar and the sacrum.

The **Extensor coccygis** is a slender muscular fasciculus, which is not always present; it extends over the lower part of the posterior surface of the sacrum and coccyx. It arises by tendinous fibres from the last segment of the sacrum, or first piece of the coccyx, and passes downwards to be inserted into the lower part of the coccyx. It is a rudiment of the Levator caudæ muscle of the lower animals.

The **Intertransversarii** are small muscles placed between the transverse processes of the vertebræ. In the *cervical region* they are best developed and consist of paired muscular and tendinous fasciculi; they pass between the anterior and the posterior tubercles respectively of the transverse processes of two contiguous vertebræ, and are separated from one another by the anterior division of the cervical nerve, which lies in the groove between them. The muscles connecting the anterior tubercles are termed the *Intertransversarii anteriores*; those between the posterior tubercles the *Intertransversarii posteriores*; both sets are supplied by the anterior divisions of the spinal nerves.

(Lickley *). There are seven pairs of these muscles, the first pair being between the atlas and epistropheus, and the last between the seventh cervical and first thoracic vertebræ. In the *thoracic region* they are present between the transverse processes of the lower three thoracic, and between the transverse processes of the last thoracic and the first lumbar vertebræ. In the *lumbar region* they are arranged in pairs, on either side of the vertebral column; one set, occupying the entire interspace between the transverse processes of the lumbar vertebræ, the *Intertransversarii laterales*; the other set, *Intertransversarii mediales*, passing from the accessory process of one vertebra to the mamillary of the vertebra below. The *Intertransversarii laterales* are supplied by the anterior divisions, and the *Intertransversarii mediales* by the posterior divisions of the spinal nerves (Lickley, *loc. cit.*).

II. SUBOCCIPITAL MUSCLES (fig. 528)

Rectus capitis posterior major.
Rectus capitis posterior minor.

Obliquus capitis inferior.
Obliquus capitis superior.

The **Rectus capitis posterior major** arises by a pointed tendon from the spinous process of the epistropheus and, becoming broader as it ascends, is inserted into the lateral part of the inferior nuchal line of the occipital bone and the surface of the bone immediately below the line. As the muscles of the two sides pass upwards and lateralwards, they leave between them a triangular space, in which the *Recti capitis posteriores minores* are seen.

The **Rectus capitis posterior minor** arises by a narrow pointed tendon from the tubercle on the posterior arch of the atlas, and, widening as it ascends, is inserted into the medial part of the inferior nuchal line of the occipital bone and the surface between it and the foramen magnum.

The **Obliquus capitis inferior**, the larger of the two Oblique muscles, arises from the apex of the spinous process of the epistropheus, and passes lateralwards and slightly upwards, to be inserted into the lower and back part of the transverse process of the atlas.

The **Obliquus capitis superior**, narrow below, wide and expanded above, arises by tendinous fibres from the upper surface of the transverse process of the atlas, joining with the insertion of the *Obliquus capitis inferior*. It passes upwards and medialwards, and is inserted into the occipital bone, between the superior and inferior nuchal lines, laterally to the *Semispinalis capitis*.

The suboccipital triangle.—This triangle is bounded, above and medially, by the *Rectus capitis posterior major*; above and laterally, by the *Obliquus capitis superior*; below and laterally, by the *Obliquus capitis inferior*. It is covered by a layer of dense fibrofatty tissue, situated beneath the *Semispinalis capitis*. The floor is formed by the posterior occipito-atlantal membrane, and the posterior arch of the atlas. In the groove on the upper surface of the posterior arch of the atlas are the vertebral artery and the first cervical nerve.

Nerves.—The deep muscles of the back and the suboccipital muscles are supplied by the posterior divisions of the spinal nerves.

Actions.—The *Sacrospinalis* and its upward continuations and the *Spinales* serve to maintain the vertebral column in the erect posture; they also serve to bend the trunk backwards when it is required to counterbalance the influence of any weight at the front of the body—as, for instance, when a heavy weight is suspended from the neck, or when there is any great abdominal distension, as in pregnancy or dropsy; the peculiar gait under such circumstances depends upon the vertebral column being drawn backwards by the counterbalancing action of the *Sacrospinales*. The muscles which form the continuation of the *Sacrospinales* on the head and neck steady those parts and fix them in the upright position. If the *Iliocostalis lumborum* and *Longissimus dorsi* of one side act, they serve to draw down the chest and vertebral column to the corresponding side. The *Iliocostalis cervicis*, taking its fixed points from the cervical vertebræ, elevates those ribs to which it is attached; taking their fixed points from the ribs, the two muscles help to extend the neck; while one bends the neck to its own side. When both *Longissimi*

cervicis act from below, they bend the neck backwards. When both *Longissimi capitis* act from below, they bend the head backwards; if only one acts, the face is turned to the side on which the muscle is acting, and then the head is bent to the shoulder. The two *Recti* draw the head backwards. The *Rectus capitis posterior major*, owing to its obliquity, rotates the skull, with the atlas, round the dens of the *epistropheus*, turning the face to the same side. The *Multifidus* acts successively upon the different parts of the column: thus, the sacrum furnishes a fixed point from which the fasciculi of this muscle act upon the lumbar region; this in turn becomes the fixed point for the fasciculi moving the thoracic region, and so on throughout the entire length of the column. The *Multifidus* serves to rotate the column, so that the front of the trunk is turned to the side opposite to that from which the muscle acts. The *Obliquus capitis superior* draws the head backwards and to its own side. The *Obliquus capitis inferior* rotates the atlas, and with it the skull, round the dens of the *epistropheus*, turning the face to the same side. When the *Semispinales* of the two sides act together, they help to extend the vertebral column; when the muscles of only one side act, they rotate the thoracic and cervical parts of the column, turning the body to the opposite side. The *Semispinales capitis* draw the head directly backwards; if one muscle acts, it draws the head to one side, and rotates it so that the face is turned to the opposite side. The *Interspinales* by approximating the spinous processes help to extend the vertebral column. The *Intertransversarii* approximate the transverse processes, and help to bend the column laterally. The *Rotatores* assist in rotating the vertebral column, so that the front of the trunk is turned to the side opposite to that from which the muscles act.

Applied Anatomy.—In cases of tuberculous caries of the vertebral bodies, and in other diseases affecting the vertebral column, rigidity of the spinal muscles is one of the earliest and most constant symptoms. A child with commencing spinal disease always maintains the affected portion of the column in a state of absolute rigidity, to prevent the inflamed structures from being moved against each other; this is one of the best examples of nature's method of producing rest of an affected part.

III. MUSCLES OF THE THORAX

<i>Intercostales externi.</i>	<i>Serratus posterior inferior.</i>
<i>Intercostales interni.</i>	<i>Serratus posterior superior.</i>
<i>Subcostales.</i>	<i>Levatores costarum.</i>
<i>Transversus thoracis.</i>	<i>Diaphragm.</i>

The *Intercostales* (fig. 549) are two thin planes of muscular and tendinous fibres occupying each of the intercostal spaces. They are named *external* and *internal* from their surface relations—the external being superficial to the internal.

The *Intercostales externi* are eleven in number on either side. Their attachments extend from the tubercles of the ribs behind, to near the cartilages of the ribs in front, where each is replaced by a layer of fascia named the *anterior intercostal membrane*, which is continued forwards to the sternum. Each arises from the lower border of a rib, and is inserted into the upper border of the rib below. In the lower two spaces they extend to the ends of the cartilages, and in the upper two or three spaces they do not quite reach the ends of the ribs. They are thicker than the *Intercostales interni*, and their fibres are directed obliquely downwards and lateralwards on the back of the thorax, and downwards, forwards, and medialwards on the front.

The *Intercostales interni* are also eleven in number on either side. Their attachments commence anteriorly at the sternum, in the interspaces between the cartilages of the true ribs, and at the anterior extremities of the cartilages of the false ribs, and extend backwards as far as the angles of the ribs, where each is replaced by a layer of fascia named the *posterior intercostal membrane*, which is continued to the vertebral column. Each arises from the ridge on the inner surface of a rib, as well as from the corresponding costal cartilage, and is inserted into the upper border of the rib below. Their fibres are also

directed obliquely, but pass in a direction opposite to those of the *Intercostales externi*.

The *Subcostales* consist of muscular and aponeurotic fasciculi, and are usually well developed only in the lower part of the thorax; each arises from the inner surface of one rib near its angle, and is inserted into the inner surface of the second or third rib below. Their fibres run in the same direction as those of the *Intercostales interni*.

The *Transversus thoracis* (*Triangularis sterni*) is a thin plane of muscular and tendinous fibres, situated upon the inner surface of the front wall of the chest (fig. 529). It arises on either side from the lower third of the posterior surface of the body of the sternum, from the posterior surface of the xiphoid process, and from the posterior surfaces of the costal cartilages of the lower three or four true ribs near their sternal ends. Its fibres diverge upwards and lateralwards, to be inserted by slips into the lower borders and inner surfaces of the costal cartilages of the second, third, fourth, fifth, and sixth ribs. The lowest fibres of this muscle are horizontal in their direction, and are continuous with those of the *Transversus abdominis*; the intermediate fibres are oblique, while the highest are almost vertical. This muscle varies in its attachments, not only in different subjects, but on opposite sides of the same subject.

The *Levatores costarum* (fig. 528), twelve in number on either side, are small tendinous and fleshy bundles, which arise from the ends of the transverse processes of the seventh cervical and upper eleven thoracic vertebrae; they pass obliquely downwards and lateralwards, like the fibres of the *Intercostales externi*, and each is inserted into the outer surface of the rib immediately below the vertebra from which it takes origin, between the tubercle and the angle (*Levatores costarum breves*). Each of the four lower muscles divides into two fasciculi, one of which is inserted as above described; the other passes down to the second rib below its origin (*Levatores costarum longi*).

The *Serratus posterior superior* is a thin, quadrilateral muscle, situated at the upper and back part of the thorax. It arises by a thin aponeurosis from the lower part of the *ligamentum nuchæ*, from the spinous processes of the seventh cervical and upper two or three thoracic vertebrae and from the *supraspinal ligament*. Inclining downwards and lateralwards it is inserted, by four fleshy digitations, into the upper borders and outer surfaces of the second, third, fourth, and fifth ribs, a little beyond their angles.

The *Serratus posterior inferior* (fig. 547) is situated at the junction of the thoracic and lumbar regions: it is of an irregularly quadrilateral form, broader than the preceding, and separated from it by a wide interval. It arises by a thin aponeurosis from the spinous processes of the lower two thoracic and upper two or three lumbar vertebrae, and from the *supraspinal ligament*; this aponeurosis is intimately blended with the *lumbodorsal fascia*. Passing

FIG. 529.—Posterior surface of sternum and costal cartilages, showing *Transversus thoracis*.

obliquely upwards and lateralwards, it becomes fleshy, and is inserted by four digitations into the inferior borders and outer surfaces of the lower four ribs, a little beyond their angles.

Nerves.—The muscles of this group are supplied by the intercostal nerves.

The **Diaphragm** (figs. 530, 531) is a dome-shaped musculofibrous septum which separates the thoracic from the abdominal cavity, its convex upper surface forming the floor of the former, and its concave under surface the roof of the latter. Its peripheral part consists of muscular fibres which take origin from the circumference of the thoracic outlet and converge to be inserted into a central tendon.

The muscular fibres may be grouped according to their origins into three parts—sternal, costal, and lumbar. The *sternal part* arises by two fleshy slips from the back of the xiphoid process; the *costal part* from the inner surfaces of the cartilages and adjacent portions of the lower six ribs on either side, interdigitating with the Transversus abdominis; and the *lumbar part*

FIG. 530.—Posterior half of Diaphragm. (Modified from model by His.)

from aponeurotic arches, named the lumbocostal arches, and from the lumbar vertebræ by two pillars or *crura*. There are two lumbocostal arches, a medial and a lateral, on either side.

The *medial lumbocostal arch* (internal arcuate ligament) is a tendinous arch in the fascia covering the upper part of the Psoas major; medially, it is continuous with the lateral tendinous margin of the corresponding crus, and is attached to the side of the body of the first or second lumbar vertebra; laterally, it is fixed to the front of the transverse process of the first lumbar vertebra.

The *lateral lumbocostal arch* (external arcuate ligament) arches across the upper part of the Quadratus lumborum, and is attached, medially, to the front of the transverse process of the first lumbar vertebra, and, laterally, to the tip and lower margin of the twelfth rib.

The crura.—At their origins the crura are tendinous in structure, and blend with the anterior longitudinal ligament of the vertebral column. The *right crus*, larger and longer than the left, arises from the anterior surfaces of the bodies and intervertebral fibrocartilages of the upper three lumbar vertebræ, while the *left crus* arises from the corresponding parts of the upper two only. The medial tendinous margins of the crura occasionally meet in the middle

line to form an arch across the front of the aorta; this arch is often poorly defined.

From this series of origins the fibres of the Diaphragm converge to be inserted into the central tendon. The fibres arising from the xiphoid process are very short, and occasionally aponeurotic; those from the medial and lateral lumbocostal arches, and more especially those from the ribs and their cartilages, are longer, and describe marked curves as they ascend and converge to their insertion. The fibres arising from the crura diverge as they ascend, the most lateral being directed upwards and lateralwards to the central tendon. The medial fibres of the right crus ascend on the left side of the œsophageal hiatus, and occasionally a fasciculus of the left crus crosses the aorta and runs obliquely through the fibres of the right crus towards the venacaval foramen (Low *).

The *central tendon* of the Diaphragm is a thin but strong aponeurosis situated near the centre of the vault formed by the muscle, but somewhat closer to the front than to the back of the thorax, so that the posterior muscular fibres are the longer. It is situated immediately below the pericardium, with which it is partially blended. It is shaped somewhat like a trefoil leaf, consisting of three divisions or leaflets separated from one another by slight indentations. The right leaflet is the largest, the middle, directed towards the xiphoid process, the next in size, and the left the smallest. In structure the tendon is composed of several planes of fibres, which intersect one another at various angles and unite into straight or curved bundles—an arrangement which gives it additional strength.

Openings in the Diaphragm.—The Diaphragm is pierced by a series of apertures to permit of the passage of structures between the thorax and abdomen. Three large openings—the aortic, the œsophageal, and the venacaval—and a number of smaller ones are present.

The *aortic hiatus* is the lowest and most posterior of the large apertures; it lies at the level of the twelfth thoracic vertebra slightly to the left of the middle line. Strictly speaking, it is not an aperture in the Diaphragm but an osseo-aponeurotic opening between it and the vertebral column, and therefore behind the Diaphragm; occasionally some tendinous fibres prolonged across the bodies of the vertebræ from the medial parts of the lower ends of the crura pass behind the aorta, and thus convert the hiatus into a fibrous ring. Through it pass the aorta, the *azygos vein*, and the thoracic duct; occasionally the *azygos vein* pierces the right crus.

The *œsophageal hiatus* is situated in the muscular part of the Diaphragm at the level of the tenth thoracic vertebra, and is elliptical in shape. It is placed above, in front, and a little to the left of the aortic hiatus, and transmits the œsophagus, the vagus nerves, and some small œsophageal vessels.

The *venacaval foramen* is the highest of the three, and is situated about the level of the fibrocartilage between the eighth and ninth thoracic vertebræ. It is quadrilateral in form, and is placed at the junction of the right and middle leaflets of the central tendon, so that its margins are tendinous. It transmits the *inferior vena cava*, the wall of which is adherent to the margin of the opening, and some branches of the *right phrenic nerve*.

Of the *lesser apertures*, two in the right crus transmit the greater and lesser right splanchnic nerves; three in the left crus give passage to the greater and lesser left splanchnic nerves and the hemiazygos vein. The gangliated trunks of the sympathetic usually enter the abdominal cavity behind the Diaphragm, under the medial lumbocostal arches. The structures piercing the crura are sometimes utilised to divide each crus into three parts—medial, intermediate, and lateral. Between the medial and intermediate crura pass the hemiazygos vein and the splanchnic nerves; between the intermediate crus and the lateral crus (which consists of the fibres rising from the medial lumbocostal arch) the gangliated trunks of the sympathetic pass.

On either side two small intervals exist at which the muscular fibres of the Diaphragm are deficient and are replaced by areolar tissue. One between the sternal and costal parts transmits the superior epigastric branch of the internal mammary artery, and some lymphatics from the abdominal wall and convex surface of the liver. The other, between the fibres springing from

* *Journal of Anatomy and Physiology*, vol. xlii.

the medial and lateral lumbocostal arches, is less constant; when this interval exists, the upper and back part of the kidney is separated from the pleura by areolar tissue only.

Relations.—The upper surface of the Diaphragm is in relation with three serous membranes, viz. on either side the pleura, which separates it from the base of the corresponding lung, and on the middle leaflet of the central tendon the pericardium, which intervenes between it and the heart. The central portion lies on a slightly lower

FIG. 531.—The Diaphragm. Under surface.

level than the summits of the lateral portions. The greater part of the under surface is covered by the peritoneum. The right side is accurately moulded over the convex surface of the right lobe of the liver, the right kidney, and right suprarenal gland; the left over the left lobe of the liver, the fundus of the stomach, the spleen, the left kidney, and the left suprarenal gland.

Nerves.—The Diaphragm is supplied by the phrenic and lower six or seven intercostal nerves.

Actions.—The Diaphragm is the principal muscle of inspiration, and presents the form of a dome concave towards the abdomen. The central part of the dome is tendinous, and the pericardium is attached to its upper surface; the circumference is muscular. During inspiration the lowest ribs are fixed, and from these and the crura the muscular fibres contract and draw downwards and forwards the central tendon with the attached pericardium. In this movement the curvature of the Diaphragm is scarcely altered, the dome moving downwards nearly parallel to its original position and pushing before it the abdominal viscera. The descent of the abdominal viscera is permitted by the extensibility of the abdominal wall, but the limit of this is soon reached. The central tendon applied to the abdominal

viscera then becomes a fixed point for the action of the Diaphragm, the effect of which is to elevate the lower ribs and through them to push forwards the body of the sternum and the upper ribs. The right cupola of the Diaphragm, lying on the liver, has a greater resistance to overcome than the left, which lies over the stomach, but to compensate for this the right crus and the fibres of the right side generally are stronger than those of the left.

The height of the Diaphragm is constantly varying during respiration; it also varies with the degree of distension of the stomach and intestines and with the size of the liver. After a forced expiration the right cupola is on a level in front with the fourth costal cartilage, at the side with the fifth, sixth, and seventh ribs, and behind with the eighth rib; the left cupola is a little lower than the right. Halls Dally * states that the absolute range of movement between deep inspiration and deep expiration averages in the male and female 30 mm. on the right side and 28 mm. on the left; in quiet respiration the average movement is 12.5 mm. on the right side and 12 mm. on the left.

In all expulsive acts the Diaphragm is called into action to give additional power to each effort. Thus, before sneezing, coughing, laughing, crying, or vomiting, and previous to the expulsion of urine or faeces, or of the foetus from the uterus, a deep inspiration takes place.

Skiagraphy shows that the height of the Diaphragm in the thorax varies considerably with the position of the body. It stands highest when the body is horizontal and the patient on his back, and in this position it performs the largest respiratory excursions with normal breathing. When the body is erect the dome of the Diaphragm falls, and its respiratory movements become smaller. The dome falls still lower when the sitting posture is assumed, and in this position its respiratory excursions are smallest. These facts may, perhaps, explain why it is that patients suffering from severe dyspnoea are most comfortable and least short of breath when they sit up. When the body is horizontal and the patient on his side, the two halves of the Diaphragm do not behave alike. The uppermost half sinks to a level lower even than when the patient sits, and moves little with respiration; the lower half rises higher in the thorax than it does when the patient is supine, and its respiratory excursions are much increased. In unilateral disease of the pleura or lungs analogous interference with the position or movement of the Diaphragm can generally be observed skiagraphically.

It appears that the position of the Diaphragm in the thorax depends upon three main factors, viz.: (1) the elastic retraction of the lung-tissue, tending to pull it upwards; (2) the pressure exerted on its under surface by the viscera: this naturally tends to be a negative pressure, or downward suction, when the patient sits or stands, and a positive, or upward pressure, when he lies; (3) the intra-abdominal tension due to the abdominal muscles. These muscles are in a state of contraction in the standing position and not in the sitting; hence the Diaphragm is pushed up higher in the former position.

The referred pains felt when the Diaphragm is inflamed are described on page 895.

The Intercostales interni and externi have probably little action in moving the ribs. They contract simultaneously and form strong elastic supports which prevent the intercostal spaces being pushed out or drawn in during respiration. The anterior portions of the Intercostales interni probably have an additional function in keeping the sternocostal and interchondral joint surfaces in apposition, the posterior parts of the Intercostales externi performing a similar function for the costovertebral articulations. The Levatores costarum being inserted near the fulcra of the ribs can have little action on the ribs: they act as rotators and lateral flexors of the vertebral column. The Transversus thoracis draws down the costal cartilages, and is therefore a muscle of expiration.

The Serrati are respiratory muscles. The Serratus posterior superior elevates the ribs and is therefore an inspiratory muscle. The Serratus posterior inferior draws the lower ribs downwards and backwards, and thus elongates the thorax; it also fixes the lower ribs, thus assisting the inspiratory action of the Diaphragm and resisting the tendency of the latter to draw the lower ribs upwards and forwards. It must therefore be regarded as a muscle of inspiration.

* *Journal of Anatomy and Physiology*, 1908, vol. xliii.

MECHANISM OF RESPIRATION

The respiratory movements must be examined during (a) quiet respiration, and (b) deep respiration.

Quiet respiration.—The first and second pairs of ribs are fixed by the resistance of the cervical structures; the last pair, and through them the eleventh, by the Quadratus lumborum. The other ribs are elevated, so that the first two intercostal spaces are diminished while the others are increased in width. It has already been shown (p. 364) that elevation of the third, fourth, fifth, and sixth ribs leads to an increase in the anteroposterior and transverse diameters of the thorax: the vertical diameter is increased by the descent of the diaphragmatic dome so that the lungs are expanded in all directions except backwards and upwards. Elevation of the eighth, ninth, and tenth ribs is accompanied by a lateral and backward movement, leading to an increase in the transverse diameter of the upper part of the abdomen; the elasticity of the anterior abdominal wall allows a slight increase in the anteroposterior diameter of this part, and in this way the decrease in the vertical diameter of the abdomen is compensated and space provided for its displaced viscera. Expiration is effected by the elastic recoil of its walls and by the action of the abdominal muscles, which push back the viscera displaced downwards by the Diaphragm.

Deep respiration.—All the movements of quiet respiration are here carried out, but to a greater extent. In deep inspiration the shoulders and the vertebral borders of the scapulæ are fixed and the limb muscles, the Trapezius, Serratus anterior, Pectorales, and Latissimus dorsi, called into play. The Scaleni are in strong action, and the Sternocleidomastoidei also assist, when the head is fixed, by drawing up the sternum and by fixing the clavicles. The first rib is therefore no longer stationary, but, with the sternum, is raised; with it all the other ribs except the last are raised to a higher level. In conjunction with the increased descent of the Diaphragm this provides for a considerable augmentation of all the thoracic diameters. The anterior abdominal muscles come into action so that the umbilicus is drawn upwards and backwards, but this allows the Diaphragm to exert a more powerful influence on the lower ribs; the transverse diameter of the upper part of the abdomen is greatly increased and the subcostal angle opened out. The deeper muscles of the back, e.g. the Serrati posteriores superiores and the Sacrospinales and their continuations, are also brought into action; the thoracic curve of the vertebral column is partially straightened, and the whole column, above the lower lumbar vertebræ, drawn backwards. This increases the anteroposterior diameters of the thorax and upper part of the abdomen and widens the intercostal spaces. Deep expiration is effected by the recoil of the walls and by the contraction of the anterolateral muscles of the abdominal wall, and the Transversus thoracis.

Halls Dally (*loc cit.*) gives the following figures as representing the average changes which occur during deepest possible respiration. The manubrium sterni moves 30 mm. in an upward and 14 mm. in a forward direction; the width of the subcostal angle, at a level of 30 mm. below the articulation between the body of the sternum and the xiphoid process, is increased by 26 mm.; the umbilicus is retracted and drawn upwards for a distance of 13 mm.

IV. MUSCLES OF THE ABDOMEN

The muscles of the abdomen may be divided into two groups: 1. The anterolateral muscles; 2. The posterior muscles.

1. ANTEROLATERAL MUSCLES

Obliquus externus.
Obliquus internus.

Transversus.
Rectus.

Pyramidalis.

The superficial fascia of the abdomen consists, over the greater part of the abdominal wall, of a single layer containing a variable amount of fat; but near the groin it is easily divisible into two layers, between which are found the superficial vessels and nerves and the superficial inguinal lymph-glands.

The superficial layer (*fascia of Camper*) is thick, areolar in texture, and contains in its meshes a varying quantity of adipose tissue. Below, it passes over the inguinal ligament, and is continuous with the superficial fascia of the thigh. In the male, Camper's fascia is continued over the penis and outer surface of the spermatic cord to the scrotum, where it helps to form the dartos. As it passes to the scrotum it changes its characteristics, becoming thin, destitute

FIG. 532.—The Obliquus externus abdominis.

of adipose tissue, and of a pale reddish colour; in the scrotum it acquires some involuntary muscular fibres and forms the *dartos tunic*. From the scrotum it may be traced backwards into continuity with the superficial fascia of the perinæum. In the female, Camper's fascia is continued from the abdomen into the labia majora.

The deep layer (*fascia of Scarpa*) is thinner and more membranous in character than the superficial, and contains a considerable quantity of yellow elastic fibres. It is loosely connected by areolar tissue to the aponeurosis of the Obliquus externus abdominis, but in the middle line it is more intimately adherent to the linea alba and to the symphysis pubis, and is prolonged on

to the dorsum of the penis, forming the *fundiform ligament*; above, it is continuous with the superficial fascia over the rest of the trunk; below and laterally, it blends with the fascia lata of the thigh a little below the inguinal ligament; medially and below, it is continued over the penis and spermatic cord to the scrotum, where it helps to form the dartos. From the scrotum it may be traced backwards into continuity with the deep layer of the superficial fascia of the perinæum (*fascia of Colles*). In the female, it is continued into the labia majora and thence to the fascia of Colles.

The *Obliquus externus abdominis* (fig. 532), situated on the lateral and anterior parts of the abdomen, is the largest and the most superficial of the three flat muscles in this region. It arises, by eight fleshy slips, from the external surfaces and inferior borders of the lower eight ribs; these slips interdigitate with the slips of origin of the *Serratus anterior* and *Latissimus dorsi*, and are arranged in an oblique line which runs downwards and backwards, the upper ones being attached close to the cartilages of the corresponding ribs, the lowest to the apex of the cartilage of the last rib, the intermediate ones to the ribs at some distance from their cartilages. From these attachments the fleshy fibres proceed in various directions. Those from the lowest ribs pass nearly vertically downwards, and are inserted into the anterior half of the outer lip of the iliac crest; the middle and upper fibres, directed downwards and forwards, end in an aponeurosis, opposite a line drawn from the prominence of the ninth costal cartilage to the anterior superior iliac spine.

The *aponeurosis* of the *Obliquus externus abdominis* is a thin but strong membranous structure, the fibres of which are directed downwards and medialwards. It is joined with that of the opposite muscle along the middle line, and the aponeuroses of the two muscles cover the front of the abdomen; above, it is covered by, and gives origin to, the lower fibres of the *Pectoralis major*; below, its fibres are closely aggregated together, and extend obliquely across from the anterior superior iliac spine to the pubic tubercle and the pectineal line. In the middle line, its fibres end in the *linea alba*, a tendinous band which extends from the xiphoid process to the symphysis pubis.

The free margin of that portion of the aponeurosis which extends between the anterior superior iliac spine and the pubic tubercle is a thick band, folded inwards, and continuous below with the fascia lata; it is called the *inguinal ligament*. The portion which is reflected from the inguinal ligament at the pubic tubercle is attached to the pecten pubis, and is called the *lacunar ligament*. From the attachment of the latter to the pecten pubis, a few fibres pass upwards and medialwards, behind the medial crus of the subcutaneous inguinal ring, to the linea alba; they diverge as they ascend, and form a thin triangular fibrous band which is called the *reflected inguinal ligament*.

In the aponeurosis of the *Obliquus externus*, immediately above the crest of the os pubis, is a triangular opening, the *subcutaneous inguinal ring*, formed by a separation of the fibres of the aponeurosis in this situation.

The following structures require further description, viz. the subcutaneous inguinal ring, the intercrural fibres and fascia, and the inguinal, lacunar, and reflected inguinal ligaments.

The *subcutaneous inguinal ring* (external abdominal ring) (figs. 532, 533) is an interval in the aponeurosis of the *Obliquus externus*, just above and lateral to the crest of the os pubis. The aperture is somewhat triangular in form, and its direction is oblique, corresponding with the course of the fibres of the aponeurosis. It measures from base to apex about 2.5 cm., and across the base about 1.25 cm. It is bounded below by the crest of the os pubis; on either side by the margins of the opening in the aponeurosis, which are called the *crura of the ring*; and above, by a series of curved *intercrural fibres*. The inferior crus (external pillar) is the stronger and is formed by that portion of the inguinal ligament which is inserted into the pubic tubercle; it is so curved as to form a kind of groove, upon which, in the male, the spermatic cord rests. The superior crus (internal pillar) is a thin, flat band, attached to the front of the symphysis pubis and interlacing with its fellow of the opposite side.

The subcutaneous inguinal ring gives passage to the spermatic cord and ilio-inguinal nerve in the male, and to the round ligament of the uterus and the ilio-inguinal nerve in the female; it is much larger in men than in women, on account of the size of the spermatic cord.

The **intercrural fibres** (intercolumnar fibres) are a series of curved tendinous fibres, which arch across the lower part of the aponeurosis of the *Obliquus externus*, describing curves with the convexities downwards. They have received their name from stretching across between the two crura of the subcutaneous inguinal ring, and they are much thicker and stronger at the inferior crus, where they are connected to the inguinal ligament, than superiorly, where they are inserted into the linea alba. The intercrural fibres increase the strength of the lower part of the aponeurosis, and tend to prevent the divergence of the crura from one another; they are more strongly developed in the male than in the female.

FIG. 533.—The subcutaneous inguinal ring

As they pass across the subcutaneous inguinal ring, they are connected together by delicate fibrous tissue, forming a fascia, called the *intercrural fascia*. This intercrural fascia is continued down as a tubular prolongation around the spermatic cord and testis, and encloses them in a sheath; hence it is also called the *external spermatic fascia*. The subcutaneous inguinal ring is seen as a distinct aperture only after the intercrural fascia has been removed.

The **inguinal ligament** (Poupart's ligament) (figs. 533, 534) is the lower border of the aponeurosis of the *Obliquus externus*, and extends from the anterior superior iliac spine to the pubic tubercle. From this latter point it is reflected backwards and lateralwards as the lacunar ligament which is attached to the pecten pubis for about 1.25 cm. Its general direction is convex downwards towards the thigh, where it is continuous with the fascia lata. Its lateral half is rounded, and oblique in direction; its medial half gradually

widens at its attachment to the os pubis, is more horizontal in direction, and supports the spermatic cord.

The **lacunar ligament** (Gimbernat's ligament) (figs. 534) is that part of the aponeurosis of the *Obliquus externus* which is reflected backwards and lateralwards, to be attached to the pecten pubis. It is of a triangular form, and is almost horizontal in direction when the body is in the erect posture; it is a little larger in the male than in the female, and measures about 2 cm. from base to apex. Its base, directed laterally, is concave, thin, and sharp, and forms the medial boundary of the femoral ring; its apex corresponds to the pubic tubercle. Its posterior margin is attached to the pecten pubis, and is continuous with the pectineal fascia; its anterior margin is attached to the inguinal ligament. Its surfaces are directed upwards and downwards.

FIG. 534.—The inguinal and lacunar ligaments.

The **reflected inguinal ligament** (triangular fascia) is a triangular-shaped layer of tendinous fibres; it is formed by an expansion from the lacunar ligament and the inferior crus of the subcutaneous inguinal ring. It passes medialwards behind the spermatic cord, expands into a somewhat fan-shaped band behind the superior crus of the subcutaneous inguinal ring and in front of the inguinal aponeurotic falx, and interlaces with the ligament of the other side at the linea alba.

Ligament of Cooper.—This is a strong fibrous band, which was first described by Sir Astley Cooper. It extends lateralwards from the base of the lacunar ligament (fig. 534) along the pecten pubis, to which it is attached. It is strengthened by the pectineal fascia, and by a lateral expansion from the lower attachment of the linea alba (*adminiculum lineæ albæ*).

The ***Obliquus internus abdominis*** (fig. 535), thinner and smaller than the *Obliquus externus*, beneath which it lies, is of an irregularly quadrilateral form. It arises, by fleshy fibres, from the lateral half of the grooved upper surface of the inguinal ligament, from the anterior two-thirds of the middle lip of the iliac crest, and from the posterior lamella of the lumbodorsal fascia. From this origin the fibres diverge; those from the inguinal ligament, few in number, and paler in colour than the rest, arch downwards and medialwards

across the spermatic cord in the male, and the round ligament of the uterus in the female, and, becoming tendinous, are inserted, conjointly with those of the Transversus, into the crest of the os pubis and into the medial part of the pecten pubis behind the lacunar ligament, forming what is known as the inguinal aponeurotic falx. Those from the anterior third of the iliac origin are horizontal in their direction, and, becoming tendinous along the lower fourth of the linea semilunaris, pass in front of the Rectus abdominis to be inserted into the linea alba. Those arising from the middle third of the iliac origin run obliquely

FIG. 535.—The Obliquus internus abdominis.

upwards and medialwards, and end in an aponeurosis; this divides at the lateral border of the Rectus into two lamellæ, which are continued forwards, one in front of and the other behind this muscle, to the linea alba; the posterior lamella has an attachment to the cartilages of the seventh, eighth, and ninth ribs. The most posterior fibres pass almost vertically upwards, to be inserted into the inferior borders of the cartilages of the three lower ribs, being continuous with the Intercostales interni.

The **Cremaster** (fig. 535) is a thin muscular layer, composed of a number of fasciculi which arise from the middle of the inguinal ligament where its fibres are continuous with those of the Obliquus internus and also occasionally with the Transversus. It passes along the lateral side of the spermatic cord, descends with it through the subcutaneous inguinal ring upon the front and sides of the cord, and forms a series of loops which differ in thickness and length in different subjects. At the upper part of the cord the loops are short, but they become successively longer, the longest reaching down as low as the

testis, where a few are inserted into the tunica vaginalis. These loops are united together by areolar tissue, and form a thin covering over the cord and testis, the *cremasteric fascia*. The fibres ascend along the medial side of the cord, and are inserted by a small pointed tendon into the tubercle and crest of the os pubis and into the front of the sheath of the Rectus abdominis.

FIG. 536.—The Transversus abdominis, Rectus abdominis, and Pyramidalis.

The Transversus abdominis (fig. 536), so called from the direction of its fibres, is the most internal of the flat muscles of the abdomen, being situated deep to the Obliquus internus. It arises by fleshy fibres from the lateral third of the inguinal ligament, from the anterior three-fourths of the inner lip of the iliac crest, from the inner surfaces of the cartilages of the lower six ribs, interdigitating with the Diaphragm, and from the lumbodorsal fascia. The muscle ends in front in a broad aponeurosis, the lower fibres of which curve downwards and medialwards, and are inserted, together with those of the Obliquus internus, into the crest of the os pubis and pecten pubis, forming

the inguinal aponeurotic falx. Throughout the rest of its extent the aponeurosis passes horizontally to the middle line, and is inserted into the linea alba; its upper three-fourths lie behind the Rectus and blend with the posterior lamella of the aponeurosis of the Obliquus internus; its lower fourth is in front of the Rectus.

The *inguinal aponeurotic falx*, or *conjoined tendon* of the Obliquus internus and Transversus, is mainly formed by the lower part of the tendon of the Transversus, and is inserted into the crest of the os pubis and pecten pubis, immediately behind the subcutaneous inguinal ring, serving to protect what would otherwise be a weak point in the abdominal wall. Lateral to the falx is a ligamentous band connected with the lower margin of the Transversus and extending down to the superior ramus of the os pubis; it is termed the *interfoveolar ligament* (of Hesselbach) (fig. 537), and sometimes contains a few muscular fibres.

FIG. 537.—The interfoveolar ligament, seen from in front. (Modified from Braune.)

The **Rectus abdominis** (fig. 536) is a long flat muscle, broader above than below, which extends along the whole length of the front of the abdomen, and is separated from its fellow of the opposite side by the linea alba. It arises by two tendons; the lateral and larger is attached to the crest of the os pubis, the medial interlaces with its fellow of the opposite side and is connected with the ligamentous fibres covering the front of the symphysis pubis. The muscle is inserted by three slips of unequal size into the cartilages of the fifth, sixth, and seventh ribs; some fibres of the upper slip are usually inserted into the anterior extremity of the fifth rib; some are occasionally connected with the costoxiphoid ligaments and the side of the xiphoid process.

The Rectus is crossed by three fibrous bands, which are named the *tendinous inscriptions*; one is usually situated opposite the umbilicus, the second opposite the free end of the xiphoid process, and the third about midway between the xiphoid process and the umbilicus. These inscriptions pass transversely or obliquely across the muscle in a zigzag course; they rarely extend completely through its substance and may pass only halfway across it; they are intimately adherent in front to the sheath of the muscle. Sometimes one or two additional but incomplete inscriptions are present below the umbilicus.

The Rectus is enclosed in a sheath (fig. 536) formed by the aponeuroses of the Obliqui and Transversus, which are arranged in the following manner. At the lateral margin of the Rectus, the aponeurosis of the Obliquus internus

divides into two lamellæ, one of which passes in front of the Rectus, blending with the aponeurosis of the Obliquus externus, the other, behind it, blending with the aponeurosis of the Transversus, and these, joining again at the medial border of the Rectus, are inserted into the linea alba. This arrangement of the aponeuroses exists from the costal margin to midway between the umbilicus and symphysis pubis, where the posterior wall of the sheath ends in a thin

FIG. 538.—Diagram of sheath of Rectus.

curved margin, the *linea semicircularis*, the concavity of which is directed downwards. In the upper part of the sheath muscular fibres of the Transversus extend into its posterior wall, and not infrequently do so to a considerable extent (fig. 538). Below the level of the *linea semicircularis* the aponeuroses of all three muscles pass in front of the Rectus; those of the Transversus and Obliquus internus are intimately fused together, but the aponeurosis of the Obliquus externus is bound to them merely by loose connective tissue except in and near the middle line; behind, the Rectus is separated from the peritoneum by the transversalis fascia (fig. 539). Since the tendons of the Obliquus internus and Transversus only reach as high as the costal margin, it follows that above this level the sheath of the Rectus is deficient posteriorly, the muscle resting directly on the cartilages of the ribs; in front, this part is covered merely by the tendon of the Obliquus externus.

The **Pyramidalis** (fig. 536) is a small triangular muscle, placed at the lower part of the abdomen, in front of the Rectus, and contained in the sheath of that muscle. It arises by tendinous fibres from the front of the os pubis and from the ligamentous fibres in front of the symphysis; the fleshy portion of the muscle passes upwards, diminishing in size as it ascends, and ends in a pointed extremity which is inserted into the linea alba midway between the umbilicus and os pubis, but may extend to a higher level. This muscle may be larger on one side than on the other, or may be wanting on one or both sides.

Besides the Rectus and Pyramidalis, the sheath of the Rectus contains the superior and inferior epigastric arteries, and the terminal portions of the lower intercostal nerves.

FIG. 539.—Diagram of a transverse section through the anterior abdominal wall, below the *linea semicircularis*.

The **linea alba** is a tendinous raphe in the middle line of the abdomen, stretching between the xiphoid process and the symphysis pubis. It is placed between the medial borders of the Recti, and is formed by the blending of the aponeuroses of the Obliqui and Transversi. It is narrow below, corresponding to the linear interval existing between the Recti; but broader above, where these muscles diverge from one another. Its lower end has a double attachment—its superficial fibres passing in front of the medial heads of the Recti to the symphysis pubis, while its deeper fibres form a triangular lamella, attached

behind the Recti to the posterior lip of the crest of the os pubis, and named the *adminiculum lineæ albe*. The linea alba presents apertures for the passage of vessels and nerves at the umbilicus, which in the foetus exists as an aperture and transmits the umbilical vessels, is closed a few days after birth.

The *lineæ semilunares* are two curved tendinous lines corresponding with the lateral borders of the Recti; each extends from the cartilage of the ninth rib to the pubic tubercle, and is formed by the aponeurosis of the Obliquus internus at its line of division to enclose the Rectus, reinforced in front by that of the Obliquus externus, and behind by that of the Transversus.

Nerves.—The abdominal muscles are supplied by the lower intercostal nerves. The Obliquus internus and Transversus also receive filaments from the anterior branch of the iliohypogastric and sometimes from the ilio-inguinal. The Cremaster is supplied by the external spermatic branch of the genitofemoral nerve, and the Pyramidalis usually by the twelfth thoracic.

Actions.—When the pelvis and thorax are fixed, the abdominal muscles compress the abdominal viscera, in which action they are materially assisted by the descent of the Diaphragm. By these means assistance is given in expelling the feces from the rectum, the urine from the bladder, the foetus from the uterus, and the contents of the stomach in vomiting.

If the pelvis and vertebral column be fixed, these muscles compress the lower part of the thorax, materially assisting expiration. If the pelvis alone be fixed, the thorax is bent directly forward when the muscles of both sides act; when the muscles of only one side contract, the trunk is bent towards that side and rotated towards the opposite side.

If the thorax be fixed, the muscles, acting together, draw the pelvis upwards, as in climbing; or, acting singly, they draw the pelvis upwards, and bend the vertebral column to one side or the other. The Recti, acting from below, depress the thorax, and consequently flex the vertebral column; when acting from above, they flex the pelvis upon the vertebral column. The Pyramidales are tensors of the linea alba.

The *transversalis fascia* is a thin aponeurotic membrane which lies between the inner surface of the Transversus muscle and the extraperitoneal fat. It forms part of the general layer of fascia lining the abdominal parietes, and is continuous with the iliac and pelvic fasciæ. In the inguinal region it is thick and dense in structure and is joined by fibres from the aponeurosis of the Transversus, but it becomes thin as it ascends to the Diaphragm, and blends with the fascia covering the under surface of this muscle. Behind, it is lost in the fat which covers the posterior surfaces of the kidneys. Below, it has the following attachments: posteriorly, to the whole length of the iliac crest, between the origins of the Transversus and Iliacus; between the anterior superior iliac spine and the femoral vessels it is connected to the posterior margin of the inguinal ligament, and is there continuous with the iliac fascia. Medially to the femoral vessels it is thin and is fixed to the pecten pubis, behind the inguinal aponeurotic falx, with which it is united; it descends in front of the femoral vessels to form the anterior wall of the femoral sheath. The spermatic cord in the male, and the round ligament of the uterus in the female, pass through the transversalis fascia at a spot called the *abdominal inguinal ring*. This opening is not visible externally since the transversalis fascia is prolonged on these structures as the infundibuliform fascia.

The *abdominal inguinal ring* (internal abdominal ring) is situated in the transversalis fascia, midway between the anterior superior iliac spine and the symphysis pubis, and about 1.25 cm. above the inguinal ligament (fig. 540). It is of an oval form, the long axis of the oval being vertical; it varies in size in different subjects, and is much larger in the male than in the female. It is bounded above by the arched lower margin of the Transversus, and medially by the inferior epigastric vessels. It transmits the spermatic cord in the male and the round ligament of the uterus in the female. From its circumference a thin funnel-shaped membrane, the *infundibuliform fascia*, is continued as a covering on the spermatic cord and testis.

The *inguinal canal* contains the spermatic cord and the ilio-inguinal nerve in the male, and the round ligament of the uterus and the ilio-inguinal nerve in the female. It is an oblique canal about 4 cm. long, slanting downwards and medialwards, and placed parallel with and a little above the inguinal ligament;

it extends from the abdominal inguinal ring to the subcutaneous inguinal ring. It is bounded *in front* by the integument, superficial fascia, and aponeurosis of the Obliquus externus throughout its whole length, and by the Obliquus internus in its lateral third; *behind* by the reflected inguinal ligament, the inguinal aponeurotic falx, the transversalis fascia, the extraperitoneal connective tissue, and the peritoneum; *above* by the arched fibres of the Obliquus internus and Transversus abdominis; *below* by the union of the transversalis fascia with the inguinal ligament, and at its medial end by the lacunar ligament.

Extraperitoneal connective tissue.—Between the inner surface of the general layer of the fascia which lines the interior of the abdominal and pelvic cavities, and the peritoneum, there is a considerable amount of connective tissue, termed the *extraperitoneal* or *subperitoneal connective tissue*.

FIG. 540.—The abdominal inguinal ring.

The *parietal* portion lines the cavity, and varies in quantity in different situations. It is especially abundant on the posterior wall of the abdomen, and particularly around the kidneys, where it contains much fat. It is scanty on the anterolateral wall of the abdomen, except in the pubic region and above the iliac crest; there is a considerable amount in the pelvis.

The *visceral* portion follows the course of the branches of the abdominal aorta between the layers of the mesenteries and other folds of peritoneum which connect the various viscera to the abdominal wall. The two portions are directly continuous with each other.

2. POSTERIOR MUSCLES OF THE ABDOMEN

Psoas major.
Psoas minor.

Iliacus.
Quadratus lumborum.

The Psoas major, the Psoas minor, and the Iliacus, with the fasciae covering them are described with the muscles of the lower extremity (see p. 513).

The fascia covering the Quadratus lumborum is a thin layer attached, medially, to the bases of the transverse processes of the lumbar vertebrae;

below, to the iliolumbar ligament; above, to the apex and lower border of the last rib. The upper margin of this fascia, which extends from the transverse process of the first lumbar vertebra to the apex and lower border of the last rib, constitutes the lateral lumbocostal arch (p. 452). Laterally, the fascia blends with the anterior layer of the lumbodorsal fascia, which intervenes between the *Quadratus lumborum* and the *Sacrospinalis*.

The *Quadratus lumborum* (fig. 528, p. 446) is irregularly quadrilateral in shape, and broader below than above. It arises by aponeurotic fibres from the iliolumbar ligament and the adjacent portion of the iliac crest for about 5 cm., and is inserted into the lower border of the last rib for about half its length, and by four small tendons into the apices of the transverse processes of the upper four lumbar vertebrae. Occasionally a second portion of this muscle is found in front of the preceding; it arises from the upper borders of the transverse processes of the lower three or four lumbar vertebrae, and is inserted into the lower margin of the last rib.

In front of the *Quadratus lumborum* are the colon, the kidney, the *Psoas major* and *minor*, and the *Diaphragm*; between the fascia and the muscle are the twelfth thoracic, iliohypogastric, and ilio-inguinal nerves.

Nerve-supply.—The twelfth thoracic and first and second lumbar nerves supply this muscle.

Actions.—The *Quadratus lumborum* draws down the last rib, and acts as a muscle of inspiration by helping to fix the origin of the *Diaphragm*. If the thorax and vertebral column are fixed, it may act upon the pelvis, raising it towards its own side when only one muscle is put in action; and when both muscles act together, either from below or above, they flex the trunk.

V. MUSCLES OF THE PELVIS

Obturator internus.
Piriformis.

Levator ani.
Coccygeus.

The muscles within the pelvis may be divided into two groups: (1) the *Piriformis* and the *Obturator internus*, which are described with the muscles of the lower extremity (pp. 523, 524); (2) the *Levator ani* and the *Coccygeus*, which together form the *pelvic diaphragm* and are associated with the pelvic viscera. The classification of the two groups under a common heading is convenient in connexion with the fasciæ investing the muscles. These fasciæ are closely related to one another and to the deep fascia of the perinæum, and in addition have special connexions with the fibrous coverings of the pelvic viscera; it is customary therefore to describe them together under the term *pelvic fascia*.

Pelvic fascia.—The fascia of the pelvis may be resolved into: (A) the fascial sheaths of the *Obturator internus*, *Piriformis*, and *pelvic diaphragm*; (B) the fascia associated with the pelvic viscera.

The *fascia of the Obturator internus* covers the pelvic surface of, and is attached round the margin of the origin of, the muscle. Above, it is loosely connected to the back part of the arcuate line, and here it is continuous with the iliac fascia. In front of this, as it follows the line of origin of the *Obturator internus*, it gradually separates from the iliac fascia and the continuity between the two is retained only through the periosteum. It arches beneath the obturator vessels and nerve, completing the obturator canal, and at the front of the pelvis is attached to the back of the superior ramus of the os pubis. Below, the obturator fascia is attached to the falciform process of the sacrotuberous ligament and to the pubic arch, where it becomes continuous with the superior fascia of the urogenital diaphragm. Behind, it is prolonged into the gluteal region.

The internal pudendal vessels and pudendal nerve cross the lower part of the pelvic surface of the *Obturator internus*, and are enclosed in a special canal—*Alcock's canal*—formed by the obturator fascia.

The *fascia of the Piriformis* is very thin and is attached to the front of the sacrum and the sides of the greater sciatic foramen; it is prolonged on the

muscle into the glutæal region. At its sacral attachment round the margins of the anterior sacral foramina it comes into intimate association with and ensheathes the nerves emerging from these foramina; hence the sacral nerves are frequently described as lying behind the fascia. The internal iliac vessels and their branches, on the other hand, lie in the subperitoneal tissue in front of the fascia, and the branches of these vessels to the glutæal region emerge in special sheaths of this tissue, above and below the Piriformis muscle.

The *diaphragmatic part of the pelvic fascia* (fig. 541) covers both surfaces of the Levatores ani. That on the inferior surface of the muscle is known as the *anal fascia*; it is attached above to the obturator fascia along the line of origin of the Levator ani, while below, it is continuous with the superior fascia of the urogenital diaphragm, and with the fascia on the Sphincter ani internus. The layer covering the upper surface of the Levator ani follows, above, the line of origin of the muscle, and is therefore somewhat variable.

FIG. 541.—Coronal section of pelvis, showing arrangement of fascia.
Viewed from behind. (Diagrammatic.)

In front it is attached to the back of the symphysis pubis about 2 cm. above its lower border, and can be traced lateralwards across the back of the superior ramus of the os pubis for a distance of about 1.25 cm., when it reaches the obturator fascia. It is attached to this fascia along a line which pursues a somewhat irregular course to the spine of the ischium. The irregularity of this line is due to the fact that the origin of the Levator ani, which in lower forms is from the pelvic brim, is in man lower down, on the obturator fascia. Tendinous fibres of origin of the muscle are therefore often found extending up towards, and in some cases reaching, the pelvic brim, and on these the fascia is carried. The lower margin of the fascia covering the upper surface of the pelvic diaphragm is attached along the line of insertion of the Levator ani.

It will be evident that the fascia covering that part of the Obturator internus which lies above the origin of the Levator ani is a composite fascia and includes the following: (a) the obturator fascia; (b) the fascia of the Levator ani; (c) degenerated fibres of origin of the Levator ani.

At the level of a line extending from the lower part of the symphysis pubis to the spine of the ischium is a thickened whitish band in this upper layer of the diaphragmatic part of the pelvic fascia. It is termed the *tendinous arch* or *white line* of the pelvic fascia, and marks the line of attachment of the special fascia (*pars endopelvina fasciæ pelyis*) which is associated with the pelvic viscera.

The *endopelvic part of the pelvic fascia* is continued over the various pelvic viscera (fig. 542), to form for them fibrous coverings which will be described later (see section on Splanchnology). It is attached to the diaphragmatic part of the pelvic fascia along the tendinous arch, and has been subdivided in accordance with the viscera to which it is related. Thus its anterior part, known as the *vesical layer*, forms the anterior and lateral ligaments of the bladder. Its middle part crosses the floor of the pelvis between the rectum

FIG. 542.—Median sagittal section of pelvis, showing arrangement of fascia.
(Diagrammatic.)

and vesiculæ seminales as the *rectovesical layer*; in the female this is perforated by the vagina. Its posterior portion, known as the *rectal layer*, passes to the side of the rectum; it forms a loose sheath for the rectum, but is firmly attached round the anal canal.

The *Levator ani* (fig. 543) is a broad, thin muscle; it is attached to the inner surface of the side of the lesser pelvis, and unites with its fellow of the opposite side to form the greater part of the floor of the pelvic cavity. It arises, in front, from the posterior surface of the superior ramus of the os pubis laterally to the symphysis; behind, from the inner surface of the spine of the ischium; and between these two points, from the obturator fascia. Posteriorly this fascial origin corresponds, more or less closely, with the tendinous arch of the pelvic fascia, but in front, the muscle arises from the fascia at a varying distance above the arch, in some cases reaching nearly as high as the canal

for the obturator vessels and nerve. The fibres pass downwards and backwards to the middle line of the floor of the pelvis; the posterior fibres are inserted into the side of the last two segments of the coccyx and into a median fibrous raphe (*anococcygeal raphe*), which extends between the coccyx and the margin of the anus. The middle fibres are inserted into the side of the anal canal, blending with those of the Sphincter muscles; lastly, the anterior fibres descend upon the side of the prostate to unite beneath it with the muscle

FIG. 548.—Left Levator ani from within.

of the opposite side, joining with the fibres of the Sphincter ani externus and Transversus perinei superficialis at the central tendinous point of the perinaeum.

The anterior portion is occasionally separated from the rest of the muscle by connective tissue. From this circumstance, as well as from its peculiar relation with the prostate, which it supports as in a sling, it has been described as a distinct muscle, under the name of *Levator prostatae*. In the female the anterior fibres of the Levator ani descend upon the side of the vagina.

The Levator ani may be divided into Iliococcygeus and Pubococcygeus.

The *Iliococcygeus* arises from the ischial spine and from the posterior part of the tendinous arch of the pelvic fascia, and is attached to the coccyx and anococcygeal raphe; it is usually thin, and may fall entirely or be largely replaced by fibrous tissue. An accessory slip at its posterior part is sometimes named the *Iliosacralis*. The *Pubococcygeus*

arises from the back of the os pubis and from the anterior part of the obturator fascia, and is directed backwards almost horizontally along the side of the anal canal. Between the coccyx and the anal canal the Pubococcygei come together and form a thick, fibromuscular layer lying on the raphe formed by the Iliococcygei. The fibres which form a sling for the rectum are named the *Puborectalis* or *Sphincter recti*; they rise from the lower part of the symphysis pubis, and from the superior fascia of the urogenital diaphragm; they meet with the corresponding fibres of the opposite side around the lower part of the rectum, and form for it a strong sling.

Symington* suggests that the Pubococcygeus should be named *Puboanal*, as it is doubtful if any of its fibres reach the coccyx.

Relations.—Its *upper* or *pelvic surface* is in relation with the diaphragmatic part of the pelvic fascia which separates it from the bladder, prostate, rectum, and peritoneum. Its *lower* or *perinæal surface* forms the medial boundary of the ischio-rectal fossa, and is covered by the inferior layer of the diaphragmatic part of the pelvic fascia (*anal fascia*). Its *posterior border* is free and separated from the Coccygeus muscle by areolar tissue. Its *anterior border* is separated from the muscle of the opposite side by a triangular space, through which the urethra, and in the female the urethra and vagina, pass from the pelvis.

Nerve-supply.—The Levator ani is supplied by a branch from the fourth sacral nerve and by a branch which is sometimes derived from the perinæal, sometimes from the inferior hæmorrhoidal, division of the pudendal nerve.

The Coccygeus (fig. 543) is situated behind the preceding. It is a triangular plane of muscular and tendinous fibres, arising by its apex from the spine of the ischium and sacrospinous ligament, and inserted by its base into the margin of the coccyx and into the side of the lowest piece of the sacrum. It assists the Levator ani and Piriformis in closing the posterior part of the outlet of the pelvis.

Nerve-supply.—The Coccygeus is supplied by a branch from the fourth and fifth sacral nerves.

Actions.—The Levatores ani constrict the lower end of the rectum and vagina. They are also muscles of forced expiration. The Coccygei pull forward and support the coccyx, after it has been pressed backwards during defæcation or parturition. The Levatores ani and Coccygei together form a muscular diaphragm which supports the pelvic viscera.

VI. MUSCLES OF THE PERINÆUM

The perinæum corresponds to the outlet of the pelvis. Its deep boundaries are—in front, the pubic arch and the ligamentum arcuatum pubis; behind, the tip of the coccyx; and on either side the inferior rami of the os pubis and ischium, and the sacrotuberous ligament. The space is somewhat lozenge-shaped and is limited on the surface of the body by the scrotum in front, by the buttocks behind, and by the medial sides of the thighs laterally. A line drawn transversely in front of the ischial tuberosities divides the space into two portions. The posterior contains the termination of the anal canal, and is known as the *anal region*; the anterior contains the external urogenital organs, and is termed the *urogenital region*.

The muscles of the perinæum may therefore be divided into two groups :

1. Those of the anal region.
2. Those of the urogenital region : A, In the male ; B, In the female.

1. MUSCLES OF THE ANAL REGION

Corrugator cutis ani. Sphincter ani externus. Sphincter ani internus.

The **superficial fascia** is very thick, areolar in texture, and contains much fat in its meshes. On either side a pad of fatty tissue extends deeply between the Levator ani and Obturator internus into a space known as the *ischio-rectal fossa*.

* *Journal of Anatomy and Physiology*, vol. xvi.

The deep fascia forms the lining of the ischio-rectal fossa; it comprises the anal fascia, and the portion of obturator fascia below the origin of Levator ani.

Ischio-rectal fossa.—The fossa is somewhat prismatic in shape, with its base directed to the surface of the perinæum, and its apex at the line of meeting of the obturator and anal fasciæ. It is bounded medially by the Sphincter ani externus and the anal fascia; laterally, by the tuberosity of the ischium and the obturator fascia; anteriorly, by the fascia of Colles covering the Transversus perinæi superficialis, and by the fascia of the urogenital diaphragm; posteriorly, by the Glutæus maximus and the sacrotuberous ligament. Crossing the space transversely are the inferior hæmorrhoidal vessels and nerves; at the posterior part are the perinæal and perforating cutaneous branches of the pudendal plexus; while from the anterior part the posterior scrotal (or labial) vessels and nerves emerge. The internal pudendal vessels and pudendal nerve lie on the lateral wall of the fossa, in Alcock's canal. The fossa is filled with fatty tissue, across which numerous fibrous bands extend from side to side.

Applied Anatomy.—Abscess in the ischio-rectal fossa commonly occurs; it is most often the result of infection from the bowel, and is especially prone to occur in tuberculous subjects; occasionally it follows perforation by a foreign body which has been swallowed, such as a fish bone. The abscess may bulge at the side of the anus, at the border of Glutæus maximus, or against the rectal wall. There is great pain on defæcation. On examining the bowel, fullness on the side of the abscess may be detected. If left to itself the pus will find exit through the skin, or into the rectum between the two Sphincters; and the condition will degenerate into one of the varieties of fistula, owing to the constant pull of the Sphincter ani externus preventing closure of the walls of the cavity. These abscesses should be opened at the earliest possible moment, as they tend to track and burrow widely into the soft fat in the fossa, and also in the subcutaneous tissues. An incision should be made tangential to the anus over the region of the ischio-rectal fossa, and should then be converted into a T, by making a second incision laterally at right angles to it, so that the wound may be kept open and may heal up from the bottom. Frequently, however, in spite of care, a fistula ensues which requires division of the Sphincter ani externus for its cure.

The Corrugator cutis ani.—Around the anus is a thin stratum of involuntary muscular fibres which radiate from the orifice. Medially the fibres fade off into the submucous tissue; laterally they blend with the true skin. By its contraction the skin around the anus is raised into ridges.

The Sphincter ani externus (fig. 544) is a flat plane of muscular fibres, elliptical in shape and intimately adherent to the skin surrounding the anus. It measures from 8 to 10 cm. in length and is about 2.5 cm. in width opposite the anus. It consists of two portions, superficial and deep. The *superficial portion*, constituting the chief part of the muscle, arises from a narrow tendinous band, the *anococcygeal raphe*, which stretches from the tip of the coccyx to the posterior margin of the anus; it forms two flattened planes of muscular tissue, which encircle the anus and meet in front to be inserted into the central tendinous point of the perinæum, joining with the Transversus perinæi superficialis, the Levator ani, and the Bulbocavernosus. The *deep portion* forms a complete sphincter to the anal canal. Its fibres surround the canal, closely applied to the Sphincter ani internus, and in front blend with the other muscles at the central point of the perinæum. In a considerable proportion of cases the fibres decussate in front of the anus, and are continuous with the Transversi perinæi superficiales. Posteriorly, they are not attached to the coccyx, but are continuous with those of the opposite side behind the anal canal. The upper edge of the muscle is ill-defined, since fibres are given off from it to join the Levator ani.

Nerve-supply.—A branch from the fourth sacral and twigs from the inferior hæmorrhoidal branch of the pudendal supply the muscle.

Actions.—The action of this muscle is peculiar. 1. It is normally in a state of tonic contraction, and having no antagonistic muscle it keeps the anal canal and orifice closed. 2. It can be put into a condition of greater contraction under the influence of the will, so as more firmly to occlude the anal aperture. 3. Taking its fixed point at the coccyx, it helps to fix the central point of the perinæum.

The **Sphincter ani internus** is a muscular ring which surrounds about 2.5 cm. of the anal canal; its inferior border is in contact with, but separate from, the **Sphincter ani externus**. It is about 5 mm. thick, and is formed by an aggregation of the involuntary circular fibres of the intestine. Its lower border is about 6 mm. from the orifice of the anus.

Actions.—Its action is entirely involuntary. It helps the **Sphincter ani externus** to occlude the anal aperture.

2. A. MUSCLES OF THE UROGENITAL REGION IN THE MALE (fig. 544)

Transversus perinæi superficialis.

Ischiocavernosus.

Bulbocavernosus.

Transversus perinæi profundus.

Sphincter urethræ membranaceæ.

Superficial fascia.—The superficial fascia of this region consists of two layers, superficial and deep.

The *superficial layer* is thick, loose, areolar in texture, and contains a variable amount of fat in its meshes. In front, it is continuous with the dartos tunic of the scrotum; behind, with the subcutaneous areolar tissue surrounding the anus; and, on either side, with the same fascia on the medial sides of the thighs. In the middle line, it is adherent to the skin of the raphe and to the deep layer of the superficial fascia.

The *deep layer of superficial fascia* (fascia of Colles) (fig. 542) is thin, aponeurotic in structure, and of considerable strength, serving to bind down the muscles of the root of the penis. It is continuous, in front, with the dartos tunic, the deep fascia of the penis, the fascia of the spermatic cord, and Scarpa's fascia upon the anterior wall of the abdomen; on either side it is attached to the margins of the rami of the os pubis and ischium, laterally to the crus penis and as far back as the tuberosity of the ischium; posteriorly, it curves round the **Transversus perinæi superficiales** to join the lower margin of the inferior fascia of the urogenital diaphragm. In the middle line, it is connected with the superficial fascia and with the median septum of the **Bulbocavernosus**. At its posterior part this fascia sends upwards from its deep surface a medial septum, which incompletely separates the posterior portion of the subjacent space into two.

The *central tendinous point of the perinæum*.—This is a fibrous point in the middle line of the perinæum, between the urethra and anus, and about 1.25 cm. in front of the latter. At this point six muscles converge and are attached: viz. the **Sphincter ani externus**, the **Bulbocavernosus**, the two **Transversi perinæi superficiales**, and the anterior fibres of the two **Levatores ani**.

The **Transversus perinæi superficialis** is a narrow muscular slip, which passes more or less transversely across the perinæal space in front of the anus. It is often feebly developed, and is sometimes absent. It arises by tendinous fibres from the medial and anterior part of the tuberosity of the ischium, and, running medialwards, is inserted into the central tendinous point of the perinæum, joining in this situation with the muscle of the opposite side, with the **Sphincter ani externus** behind, and with the **Bulbocavernosus** in front. In some cases, the fibres of the deeper layer of the **Sphincter ani externus** decussate in front of the anus and are continued into this muscle. Occasionally it gives off fibres, which join with the **Bulbocavernosus** of the same side.

Actions.—The simultaneous contraction of the two muscles serves to fix the central tendinous point of the perinæum.

The **Bulbocavernosus** (*Ejaculator urinæ*) is placed in the middle line of the perinæum, in front of the anus, and consists of two symmetrical parts, united along the median line by a tendinous raphe. It arises from the central tendinous point of the perinæum and from the median raphe in front. Its fibres diverge like the barbs of a quill-pen; the most posterior form a thin layer, which is lost on the inferior fascia of the urogenital diaphragm; the middle fibres encircle the bulb and adjacent parts of the corpus cavernosum urethræ, and are inserted into a strong aponeurosis on the upper part of the corpus cavernosum urethræ; the anterior fibres spread out over the side of the corpus

Between the muscles just examined a triangular space exists, bounded medially by the Bulbocavernosus, laterally by the Ischiocavernosus, and behind by the Transversus perinæi superficialis; the floor is formed by the inferior fascia of the urogenital diaphragm. Running from behind forwards in the space are the posterior scrotal vessels and nerves, and the perinæal branch of the posterior femoral cutaneous nerve; the transverse perinæal artery courses along its posterior boundary on the Transversus perinæi superficialis.

The deep fascia of the urogenital region forms an investment for the Transversus perinæi profundus and the Sphincter urethræ membranaceæ, but within it lie also the deep vessels and nerves of this part, the whole forming a transverse septum which is known as the *urogenital diaphragm*. From its shape this part of the deep fascia is sometimes termed the *triangular ligament*, and it is stretched almost horizontally across the pubic arch, so as to close the anterior part of the pelvic outlet. It consists of two dense membranous laminae (fig. 545), which are united along their posterior borders, but are

FIG. 545.—Coronal section of anterior part of pelvis, through the pubic arch. Seen from in front. (Diagrammatic.)

separated in front by intervening structures. The superficial of these two layers, the *inferior fascia of the urogenital diaphragm* (superficial layer of the triangular ligament), is triangular in shape, and about 4 cm. in depth. Its apex is directed forwards, and is separated from the arcuate pubic ligament by an oval opening for the transmission of the deep dorsal vein of the penis. Its lateral margins are attached on either side to the inferior rami of the os pubis and ischium, above the crus penis. Its base is directed towards the anus, and connected to the central tendinous point of the perinæum. It is continuous with the deep layer of the superficial fascia behind the Transversus perinæi superficialis, and with the inferior layer of the diaphragmatic part of the pelvic fascia (anal fascia). It is perforated, about 2.5 cm. below the symphysis pubis, by the urethra, the aperture for which is circular and about 6 mm. in diameter; by the arteries and nerves to the bulb and the ducts of the bulbo-urethral glands close to the urethra; by the deep arteries of the penis, one on either side close to the pubic arch and about halfway along the attached margin of the fascia; by the dorsal arteries and nerves of the penis near the apex of the fascia. Its base is also perforated by the posterior scrotal vessels and nerves, while between its apex and the arcuate pubic ligament the deep dorsal vein of the penis passes upwards into the pelvis.

If the inferior fascia of the urogenital diaphragm be detached, the following structures will be seen between it and the superior fascia: the deep dorsal vein of the penis, the membranous portion of the urethra, the *Transversus perinæi profundus* and *Sphincter urethræ membranaceæ* muscles, the bulbourethral glands and their ducts, the pudendal vessels and dorsal nerves of the penis, the arteries and nerves of the urethral bulb, and a plexus of veins.

The *superior fascia of the urogenital diaphragm* (deep layer of the triangular ligament) is continuous with the obturator fascia and stretches across the pubic arch. If the obturator fascia be traced medially after leaving the *Obturator internus* muscle, it will be found attached by some of its deeper or anterior fibres to the inner margin of the pubic arch, while its superficial or posterior fibres pass over this attachment to become continuous with the superior fascia of the urogenital diaphragm. Behind, this layer of the fascia is continuous with the inferior fascia of the urogenital diaphragm and with the fascia of Colles: in front it is continuous with the fascial sheath of the prostate, and is fused with the inferior fascia to form the *transverse ligament of the pelvis*.

The *Transversus perinæi profundus* arises from the inferior rami of the ischium and runs to the median line, where it interlaces in a tendinous raphe with its fellow of the opposite side. It lies in the same plane as the *Sphincter urethræ membranaceæ*; formerly the two muscles were described together as the *Constrictor urethræ*.

The *Sphincter urethræ membranaceæ* surrounds the membranous portion of the urethra, and is enclosed in the fascia of the urogenital diaphragm. Its external fibres arise from the junction of the inferior rami of the os pubis and ischium, to the extent of 1.25 or 2 cm., and from the neighbouring fasciæ. They arch across the front of the urethra and bulbourethral glands, pass round the urethra, and behind unite with the muscle of the opposite side, by means of a tendinous raphe. Its internal fibres form a continuous circular investment for the membranous urethra.

Actions.—The muscles of both sides act together as a sphincter, compressing the membranous portion of the urethra. During the transmission of fluids they, like the *Bulbocavernosus*, are relaxed, and only come into action at the end of the process to eject the last drops.

Nerve-supply.—The perineal branch of the pudendal nerve supplies this group of muscles.

2. B. MUSCLES OF THE UROGENITAL REGION IN THE FEMALE (fig. 546)

Transversus perinæi superficialis.

Ischiocavernosus.

Bulbocavernosus.

Transversus perinæi profundus.

Sphincter urethræ membranaceæ.

The *Transversus perinæi superficialis* in the female is a narrow muscular slip, which arises by a small tendon from the inner and fore part of the tuberosity of the ischium, and is inserted into the central tendinous point of the perinæum, joining in this situation with the muscle of the opposite side, the *Sphincter ani externus* behind, and the *Bulbocavernosus* in front.

Action.—The simultaneous contraction of the two muscles serves to fix the central tendinous point of the perinæum.

The *Bulbocavernosus* (*Sphincter vaginæ*) surrounds the orifice of the vagina. It covers the lateral parts of the vestibular bulbs, and is attached posteriorly to the central tendinous point of the perinæum, where it blends with the *Sphincter ani externus*. Its fibres pass forwards on either side of the vagina, to be inserted into the corpora cavernosa clitoridis, a fasciculus crossing over the body of the organ so as to compress the deep dorsal vein.

Actions.—The *Bulbocavernosus* diminishes the orifice of the vagina. The anterior fibres contribute to the erection of the clitoris by the compression of its deep dorsal vein.

The *Ischiocavernosus* (*Erector clitoridis*), smaller than the corresponding muscle in the male, covers the unattached surface of the crus clitoridis. It arises by tendinous and fleshy fibres from the inner surface of the tuberosity

of the ischium, behind the crus clitoridis; from the surface of the crus; and from the adjacent portion of the ramus of the ischium. The muscular fibres end in an aponeurosis which is inserted into the sides and under surface of the crus clitoridis.

Actions.—The Ischiocavernosus compresses the crus clitoridis and retards the return of blood through the veins, and thus serves to maintain the clitoris erect.

The *fascia of the urogenital diaphragm* in the female is not so strong as in the male. It is attached to the pubic arch, its apex being connected with the arcuate pubic ligament. It is divided in the middle line by the aperture of the vagina; with the external coat of which it blends, and in front of this it is perforated by the urethra. Its posterior border is continuous with the deep layer of the superficial fascia around the Transversus perinæi superficialis.

FIG. 546.—Muscles of the female perinæum. (Modified from a drawing by Peter Thompson.)

Like the corresponding fascia in the male, it consists of two layers, between which are to be found the following structures: the deep dorsal vein of the clitoris, a portion of the urethra, the Transversus perinæi profundus and Sphincter urethræ membranaceæ muscles, the greater vestibular glands and their ducts, the internal pudendal vessels and the dorsal nerves of the clitoris, the arteries and nerves of the bulbi vestibuli, and a plexus of veins.

The Transversus perinæi profundus arises from the inferior rami of the ischium and runs across to the side of the vagina.

The Sphincter urethræ membranaceæ, like the corresponding muscle in the male, consists of external and internal fibres. The external fibres arise on either side from the margin of the inferior ramus of the os pubis. They are directed across the pubic arch in front of the urethra, and pass round it to blend with the muscular fibres of the opposite side, between the urethra and vagina. The innermost fibres encircle the lower end of the urethra.

Nerve-supply.—The muscles of this group are supplied by the perinæal branch of the pudendal nerve.

FASCIÆ AND MUSCLES OF THE UPPER EXTREMITY

The muscles of the upper extremity are divisible into the following groups :

- I. Muscles connecting the upper extremity with the vertebral column.
- II. Muscles connecting the upper extremity to the anterior and lateral thoracic walls.
- III. Muscles of the shoulder.
- IV. Muscles of the arm.
- V. Muscles of the forearm.
- VI. Muscles of the hand.

I. MUSCLES CONNECTING THE UPPER EXTREMITY WITH THE VERTEBRAL COLUMN

Trapezius.	Rhomboideus major.
Latissimus dorsi.	Rhomboideus minor.
Levator scapulæ.	

The superficial fascia of the back forms a layer of considerable thickness and strength, and contains a quantity of granular fat. It is continuous with the general superficial fascia.

The deep fascia is a dense fibrous layer, attached above to the superior nuchal line of the occipital bone ; in the middle line it is fixed to the ligamentum nuchæ and supraspinal ligament, and to the spinous processes of all the vertebræ below the seventh cervical : laterally, in the neck it is continuous with the fascia colli ; over the shoulder it is attached to the spine of the scapula and to the acromion, and is continued downwards over the Deltoidæus to the arm ; on the thorax it is continuous with the deep fascia of the axilla and chest, and on the abdomen with that covering the abdominal muscles ; below, it is attached to the crest of the ilium.

The **Trapezius** (fig. 547) is a flat, triangular muscle, covering the back of the neck and shoulder. It arises from the medial third of the superior nuchal line of the occipital bone, the external occipital protuberance, the ligamentum nuchæ, the spinous process of the seventh cervical, and the spinous processes of all the thoracic vertebræ, and the corresponding portion of the supraspinal ligament. The superior fibres proceed downwards and lateralwards, the inferior upwards and lateralwards, and the middle horizontally ; the superior fibres are inserted into the posterior border of the lateral third of the clavicle ; the middle fibres into the medial margin of the acromion and the superior lip of the posterior border of the spine of the scapula ; the inferior fibres converge and end in an aponeurosis, which glides over the smooth triangular surface on the medial end of the spine of the scapula, a bursa being interposed, and is inserted into a tubercle at the apex of this smooth triangular surface. The upper part of the Trapezius is connected to the occipital bone by a thin fibrous lamina, firmly adherent to the skin ; the middle part arises by a broad semi-elliptical aponeurosis, which reaches from the sixth cervical to the third thoracic vertebra ; the lower part arises by short tendinous fibres. The two Trapezius muscles together resemble a trapezium, or quadrangle ; two angles corresponding to the shoulders ; a third to the occipital protuberance ; and the fourth to the spinous process of the twelfth thoracic vertebra.*

The clavicular insertion of this muscle varies in extent : it sometimes reaches as far as the middle of the clavicle, and occasionally blends with or overlaps the posterior edge of the Sternocleidomastoideus.

The **Latissimus dorsi** (fig. 547) is a large triangular, flat muscle, which covers the lumbar region and the lower half of the thoracic region ; but its fibres converge to a narrow tendon of insertion. It arises by tendinous fibres from the spinous processes of the lower six thoracic vertebræ in front of the Trapezius, and from the posterior layer of the lumbodorsal fascia (p. 444), by which it is attached to the spines of the lumbar and sacral vertebræ to the

* The two muscles cover the back of the neck and shoulders like a monk's cowl, and therefore the Trapezius is sometimes termed the *Musculus cucullaris*.

FIG. 547.—Muscles connecting the upper extremity to the vertebral column.

supraspinal ligament; and to the posterior part of the crest of the ilium. In addition, it arises by muscular fibres from the external lip of the crest of the ilium lateral to the margin of the Sacrospinalis, and from the three or four lower ribs by fleshy digitations which are interposed between similar processes of the Obliquus abdominis externus (fig. 532, p. 457). From this extensive origin the fibres pass in different directions, the upper ones horizontally, the middle obliquely upwards, and the lower almost vertically upwards, so as to converge and form a thick fasciculus, the upper part of which crosses, and usually receives a few fibres from, the inferior angle of the scapula. The muscle curves around the lower border of the Teres major, and is twisted upon itself, so that the superior fibres become at first posterior and then inferior, and the ascending fibres at first anterior and then superior. It ends in a quadrilateral tendon, about 7 cm. long, which passes in front of the tendon of the Teres major, and is inserted into the bottom of the intertubercular sulcus of the humerus, giving an expansion to the deep fascia of the arm; its insertion extends higher on the humerus than that of the tendon of the Pectoralis major. The lower border of its tendon is united with that of the Teres major, the surfaces of the two tendons being separated near their insertions by a bursa; another bursa is sometimes interposed between the muscle and the inferior angle of the scapula.

A muscular slip, the *axillary arch*, varying from 7 to 10 cm. in length, and from 5 to 15 mm. in breadth, occasionally springs from the upper edge of the Latissimus dorsi about the middle of the posterior fold of the axilla, and crosses the axilla in front of the axillary vessels and nerves, to join the under surface of the tendon of the Pectoralis major, the Coracobrachialis, or the fascia over the Biceps brachii. This axillary arch crosses the axillary artery, just above the spot usually selected for the application of a ligature, and may mislead the surgeon during the operation. It is present in about seven per cent. of subjects and may be easily recognised by the direction of its fibres.

A fibrous slip usually passes from the lower border of the tendon of the Latissimus dorsi, near its insertion, to the long head of the Triceps brachii. This is occasionally muscular, and is the representative of the *Dorsoepitrochlearis brachii* of apes.

The lower part of the lateral margin of the Latissimus dorsi is separated from the Obliquus externus abdominis by a small triangular interval, the *lumbar triangle* (of Petit), the base of which is formed by the iliac crest, and its floor by the Obliquus internus abdominis. Another triangle, known as the *triangle of auscultation*, is situated behind the scapula. It is bounded above by the Trapezius, below by the Latissimus dorsi, and laterally by the vertebral border of the scapula; the floor is partly formed by the Rhomboideus major. If the scapula be drawn forwards by folding the arms across the chest, and the trunk bent forwards, parts of the sixth and seventh ribs and the interspace between them become subcutaneous and available for auscultation.

Nerves.—The Trapezius is supplied by the accessory nerve, and by branches from the third and fourth cervical nerves; the Latissimus dorsi by the fifth, sixth, and seventh cervical nerves through the thoracodorsal (long subscapular) nerve.

The **Rhomboideus major** (fig. 547) arises by tendinous fibres from the spinous processes of the second, third, fourth, and fifth thoracic vertebræ and the supraspinal ligament. The fibres of the muscle are directed downwards and lateralwards and are inserted into the vertebral border of the scapula between the triangular surface of the root of the spine and the inferior angle. Usually the insertion is an indirect one, the muscular fibres ending in a tendinous arch which is fixed at its ends to the two points mentioned and joined to the vertebral border by a thin membrane; occasionally the arch is incomplete, and some of the muscular fibres are then inserted directly into the scapula.

The **Rhomboideus minor** (fig. 547) arises from the lower part of the ligamentum nuchæ and from the spinous processes of the seventh cervical and first thoracic vertebræ; it is inserted into the base of the triangular smooth surface at the root of the spine of the scapula. It is usually separated from the Rhomboideus major by a slight interval, but the adjacent margins of the two muscles are occasionally united.

The **Levator scapulae** (fig. 547) is situated at the back and side of the neck. It arises by tendinous slips from the transverse processes of the atlas and Axis and from the posterior tubercles of the transverse processes of the

third and fourth cervical vertebræ. It is inserted into the vertebral border of the scapula, between the medial angle and the triangular smooth surface at the root of the spine.

Nerves.—The Rhomboidei are supplied by the fifth cervical through the dorsal scapular nerve; the Levator scapulæ by the third and fourth cervical nerves, and frequently by a branch from the dorsal scapular.

Actions.—When the whole Trapezii is in action it retracts the scapula and braces back the shoulder; if the head be fixed, the upper part of the muscle will elevate the point of the shoulder, as in supporting weights; when the lower fibres contract they assist in depressing the scapula. The middle and lower fibres of the muscle rotate the scapula. If the shoulders be fixed, the Trapezii, acting together, will draw the head directly backwards; or if only one act, the head is drawn to the corresponding side.

When the Latissimus dorsi acts upon the humerus, it depresses and draws it backwards, and at the same time rotates it inwards. It is the muscle which is principally employed in giving a downward blow, as in felling a tree or in sabre practice. If the arm be fixed, the muscle may act in various ways upon the trunk: thus, it may raise the lower ribs and assist in forcible inspiration; or, if both arms be fixed, the two muscles may assist the abdominal muscles and Pectorales in suspending and drawing the trunk upwards and forwards, as in climbing.

The Rhomboidei carry the inferior angle backwards and upwards, thus producing a slight rotation of the scapula upon the side of the chest, the Rhomboideus major acting especially on the inferior angle of the scapula, through the tendinous arch by which it is inserted. The Rhomboidei, acting together with the middle and inferior fibres of the Trapezii, will retract the scapula.

If the head be fixed, the Levator scapulæ raises the medial angle of the scapula; if the shoulder be fixed, the muscle inclines the neck to the corresponding side and rotates it in the same direction.

II. MUSCLES CONNECTING THE UPPER EXTREMITY TO THE ANTERIOR AND LATERAL THORACIC WALLS

Pectoralis major.
Pectoralis minor.

Subclavius.
Serratus anterior.

The **superficial fascia** of the anterior thoracic region is continuous with that of the neck and upper extremity above, and of the abdomen below. It encloses the mamma and gives off numerous septa which pass into the gland to support its various lobes. From the fascia over the front of the mamma, fibrous processes pass forwards to the integument and mammary papilla; these were called by Sir A. Cooper the *ligamenta suspensoria*.

The **pectoral fascia** is a thin lamina, covering the surface of the Pectoralis major, and sending numerous prolongations between its fasciuli; it is attached, in the middle line, to the front of the sternum; above, to the clavicle; laterally and below, it is continuous with the fascia of the shoulder, axilla, and thorax. It is very thin over the upper part of the Pectoralis major, but thicker in the interval between it and the Latissimus dorsi, where it closes in the axillary space and forms the *axillary fascia*; this divides at the lateral margin of the Latissimus dorsi into two layers, one of which passes in front of, and the other behind this muscle; these proceed as far as the spinous processes of the thoracic vertebræ, to which they are attached. As the fascia leaves the lower edge of the Pectoralis major to cross the floor of the axilla it sends a layer upwards under cover of the muscle; this lamina splits to envelop the Pectoralis minor, and at the upper edge of this muscle is continuous with the coracoclavicular fascia. The hollow of the armpit, seen when the arm is abducted, is produced mainly by the traction of this fascia on the axillary floor, and hence the lamina is sometimes named the *suspensory ligament* of the axilla. At the lower part of the thoracic region the deep fascia is well developed, and is continuous with the fibrous sheath of the Rectus abdominis.

Applied Anatomy.—In cases of suppuration in the axilla, the pus is prevented from extending downwards by the axillary fascia, and therefore tends to spread upwards, beneath the pectoral muscles, towards the root of the neck. Early evacuation of the pus

is therefore necessary. The incision should be made midway between the anterior and posterior axillary folds, so as to avoid the lateral thoracic and subscapular vessels, and the edge of the knife should be directed away from the axillary vessels.

The **Pectoralis major** (fig. 548) is a thick, triangular muscle situated at the upper and front part of the chest. It arises from the anterior surface of the sternal half of the clavicle; from half the breadth of the anterior surface of the sternum, as low down as the attachment of the cartilage of the sixth or

FIG. 548.—Superficial muscles of the chest and front of the arm.

seventh rib; from the cartilages of all the true ribs, with the exception, frequently, of the first, or seventh, or both, and from the aponeurosis of the *Obliquus externus abdominis*. From this extensive origin the fibres converge towards their insertion; those arising from the clavicle pass obliquely downwards and lateralwards, and are usually separated from the rest by a slight interval; those from the lower part of the sternum, and the cartilages of the lower true ribs, run upwards and lateralwards; while the middle fibres pass horizontally. They all end in a flat tendon, about 5 cm. broad, which is inserted into the crest of the greater tubercle of the humerus. This tendon consists of two laminae, placed one in front of the other, and usually blended together

below. The anterior lamina, the thicker, receives the clavicular and the uppermost sternal fibres; they are inserted in the same order as that in which they arise: that is to say, the most lateral of the clavicular fibres are inserted at the upper part of the anterior lamina; the uppermost sternal fibres pass down to the lower part of the lamina, which extends as low as the tendon of the Deltoides and joins with it. The posterior lamina of the tendon receives the attachment of the greater part of the sternal portion and the deep fibres, i.e. those from the costal cartilages. These deep fibres, and particularly those from the lower costal cartilages, turn backwards successively behind and reach a higher level than the superficial and upper ones, so that the tendon appears to be twisted. The posterior lamina of the tendon reaches higher on the humerus than the anterior, and gives off an expansion which covers the intertubercular sulcus and blends with the capsule of the shoulder-joint. From the deepest fibres of this lamina at its insertion an expansion is given off which lines the intertubercular sulcus, while from the lower border of the tendon a third expansion passes downwards to the fascia of the arm.

Relations.—In front of the Pectoralis major are the skin, superficial fascia, Platysma, anterior and middle supraclavicular nerves, mamma, and deep fascia; its *posterior surface* is in contact with the sternum, ribs and costal cartilages, coracoclavicular fascia, Subclavius, Pectoralis minor, Serratus anterior, and Intercostales; it forms the anterior wall of the axillary space, and covers the axillary vessels and nerves and the upper parts of the Biceps brachii and Coracobrachialis. Its *upper border* is separated from the Deltoides by a slight interspace, the *deltoideopectoral triangle*, or *infraclavicular fossa*, in which the cephalic vein and deltoid branch of the thoraco-acromial artery lie. Its *lower border* forms the anterior fold of the axilla; it is separated from the Latissimus dorsi by a considerable interval at the medial wall of the axilla; but the two muscles gradually converge towards the lateral wall of the space.

The coracoclavicular fascia (costocoracoid membrane) is a strong fascia situated under cover of the clavicular portion of the Pectoralis major. It occupies the interval between the Pectoralis minor and Subclavius, and protects the axillary vessels and nerves. Traced upwards, it splits to enclose the Subclavius, and is attached to the clavicle, in front of and behind the muscle; the layer behind the muscle fuses with the deep cervical fascia and with the sheath of the axillary vessels. Medially, it blends with the fascia covering the first two intercostal spaces, and is attached also to the first rib medial to the origin of the Subclavius. Laterally, it is thick and dense, and is attached to the coracoid process. The portion extending from the first rib to the coracoid process is often stronger than the rest, and is sometimes called the *costocoracoid ligament*. Below this, the fascia is thin; it splits to ensheath the Pectoralis minor; and from the lower border of this muscle is continued downwards to join the axillary fascia, and lateralwards to unite with the fascia covering the short head of the Biceps brachii. The coracoclavicular fascia is pierced by the cephalic vein, thoraco-acromial artery and vein, and lateral anterior thoracic nerve.

The Pectoralis minor (fig. 549) is a thin, triangular muscle, situated at the upper part of the thorax, beneath the Pectoralis major. It arises from the upper margins and outer surfaces of the third, fourth, and fifth ribs, near their cartilages, and from the aponeuroses covering the Intercostales externi; the fibres pass upwards and lateralwards, and converge to form a flat tendon, which is inserted into the medial border and upper surface of the coracoid process of the scapula.

Relations.—Its *anterior surface* is in relation with the Pectoralis major, the lateral anterior thoracic nerve, and the pectoral branch of the thoraco-acromial artery; its *posterior surface*, with the ribs, Intercostales externi, Serratus anterior, the axillary space, and the axillary vessels and brachial plexus of nerves. Its *upper border* is separated from the clavicle by a narrow triangular interval occupied by the coracoclavicular fascia, behind which are the axillary vessels and nerves. Running parallel with the *lower border* of the muscle is the lateral thoracic artery, and piercing the muscle is the medial anterior thoracic nerve.

The Subclavius (fig. 549) is a small triangular muscle, placed between the clavicle and first rib. It arises by a short, thick tendon from the first rib and its cartilage at their junction, in front of the costoclavicular ligament;

the fleshy fibres proceed obliquely upwards and lateralwards, to be inserted into the groove on the under surface of the clavicle between the costoclavicular and coracoclavicular ligaments.

Relations.—Its *posterior surface* is separated from the first rib by the subclavian vessels and brachial plexus of nervos. Its *anterior surface* is separated from the Pectoralis major by the coracoclavicular fascia, which, with the clavicle, forms an osseofibrous sheath for the muscle.

The **Serratus anterior** (Serratus magnus) (fig. 549) is a muscular sheet, situated between the ribs and scapula at the upper and lateral part of the

FIG. 549.—Deep muscles of the chest and front of the arm.

chest. It arises by fleshy slips or digitations from the outer surfaces and superior borders of the upper eight or nine ribs, and from the aponeuroses covering the intervening Intercostales. Each digitation (except the first) arises from the corresponding rib; the first springs from the first and second ribs, and from the fascia covering the first intercostal space. The lower four slips interdigitate with the upper five slips of the Obliquus externus abdominis. From this extensive attachment the fibres pass backwards, closely applied to the chest-wall, and reach the vertebral border of the scapula, and are inserted into its ventral surface in the following manner. The first digitation is inserted into a triangular area on the ventral surface of the medial angle. The next two or three digitations spread out to form a thin, triangular sheet, the base of which is directed backwards and is inserted into nearly the whole length of the ventral surface of the vertebral border. The lower five or six digitations converge to form a fan-shaped mass, the apex of which is inserted, by muscular

and tendinous fibres, into a triangular impression on the ventral surface of the inferior angle.

Nerves.—The Pectoralis major is supplied by the medial and lateral anterior thoracic nerves; through these nerves the muscle receives filaments from all the spinal nerves entering into the formation of the brachial plexus. The Pectoralis minor receives its fibres from the eighth cervical and first thoracic nerves through the medial anterior thoracic nerve. The Subclavius is supplied by a filament from the fifth and sixth cervical nerves. The Serratus anterior is supplied by the long thoracic, which is derived from the fifth, sixth, and seventh cervical nerves.

Actions.—If the arm has been raised by the Deltoides, the Pectoralis major will, conjointly with the Latissimus dorsi and Teres major, depress it to the side of the chest. If acting alone, it adducts and draws forwards the arm, bringing it across the front of the chest, and at the same time rotates it inwards. The Pectoralis minor depresses the point of the shoulder, drawing the scapula downwards and medialwards towards the thorax, and throwing the inferior angle backwards. The Subclavius depresses the shoulder, carrying it downwards and forwards. When the arms are elevated and fixed, all three muscles act upon the ribs, drawing them upwards and expanding the chest, and thus assisting in forced inspiration. The Serratus anterior, as a whole, carries the scapula forwards, and at the same time raises the vertebral border of the bone. It is, therefore, concerned in the action of pushing. Its lower and stronger fibres move the lower angle forwards and assist the Trapezius in rotating the bone at the sternoclavicular joint, and thus aid this muscle in raising the acromion and supporting weights upon the shoulder. It is also an assistant to the Deltoides in raising the arm, inasmuch as during the action of this latter muscle it fixes the scapula and so steadies the glenoid cavity on which the head of the humerus rotates. After the Deltoides has raised the arm to a right angle with the trunk, the Serratus anterior and the Trapezius, by rotating the scapula, raise the arm into an almost vertical position. It is possible that when the shoulders are fixed the lower fibres of the Serratus anterior may assist in raising and everting the ribs; but it is not the important inspiratory muscle it was formerly believed to be.

Applied Anatomy.—When the Serratus anterior is paralysed, the vertebral border, and especially the lower angle of the scapula, leave the ribs and stand out prominently on the surface, giving a peculiar 'winged' appearance to the back (p. 271). The patient is unable to raise the arm, and an attempt to do so is followed by a further projection of the lower angle of the scapula from the back of the thorax.

III. MUSCLES OF THE SHOULDER

Deltoides.
Subscapularis.
Supraspinatus.

Infraspinatus.
Teres minor.
Teres major.

The deep fascia covering the Deltoides invests the muscle, and sends numerous septa between its fasciculi. In front, it is continuous with the pectoral fascia; behind, where it is thick and strong, with the fascia infraspinata; above, it is attached to the clavicle, the acromion, and the spine of the scapula; below, it is continuous with the brachial fascia.

The Deltoides (fig. 548) is a thick, triangular muscle, which covers the shoulder-joint. It arises from the anterior border and upper surface of the lateral third of the clavicle; from the lateral margin and upper surface of the acromion, and from the lower lip of the posterior border of the spine of the scapula, as far back as the triangular surface at its medial end. The fibres converge towards their insertion, the middle passing vertically, the anterior inclining backwards, and the posterior forwards; they unite in a thick tendon which is inserted into the deltoid tuberosity on the middle of the lateral side of the body of the humerus. At its insertion the tendon gives off an expansion to the deep fascia of the arm. This muscle is remarkably coarse in texture, and the part arising from the acromion consists of oblique fibres; these arise in a bipennate manner from the sides of tendinous septa, generally four in number, which pass downwards from the acromion into the muscle. These oblique fibres are inserted into similar tendinous septa, generally

three in number, which ascend from the insertion of the muscle and alternate with the descending septa. The portions of the muscle arising from the clavicle and spine of the scapula are not arranged in this manner, but are inserted into the margins of the inferior tendon.

Relations.—Its *superficial surface* is in relation with the skin, the superficial and deep fasciæ, Platysma, posterior supraclavicular, and lateral brachial cutaneous nerves. Its *deep surface* is separated from the articular capsule of the shoulder-joint by a large bursa, and covers the coracoid process, coraco-acromial ligament, Pectoralis minor, Coracobrachialis, both heads of the Biceps brachii, the tendon of the Pectoralis major, the insertions of the Supraspinatus, Infraspinatus, and Teres minor, the long and lateral heads of the Triceps brachii, the humeral circumflex vessels, the axillary nerve, and the upper part of the body of the humerus. Its *anterior border* is separated at its upper part from the Pectoralis major by the deltoideopectoral triangle in which the cephalic vein and deltoid branch of the thoraco-acromial artery lie; lower down the two muscles are in close contact. Its *posterior border* rests on the Infraspinatus and Triceps brachii.

Nerves.—The Deltoideus is supplied by the fifth and sixth cervical nerves through the axillary nerve.

Actions.—The Deltoideus raises the arm from the side, so as to bring it at right angles with the trunk. Its anterior fibres, assisted by the Pectoralis major, draw the arm forwards; and its posterior fibres, aided by the Teres major and Latissimus dorsi, draw it backwards.

Applied Anatomy.—The Deltoideus is very liable to atrophy, and in this condition dislocation of the shoulder-joint is simulated, as there is flattening of the shoulder and apparent prominence of the acromion; the distance also between the acromion and the head of the bone is increased, and the tips of the fingers can be inserted between them. Atrophy of the Deltoideus may be due to disuse, such as follows chronic arthritis or permanent injury of the shoulder-joint. It also frequently results from degenerations occurring in the medulla spinalis, or injury to the axillary nerve ('crutch-palsy'). The Deltoideus, Supraspinatus, and Infraspinatus often escape in myopathic atrophies affecting the other muscles of the upper arm or shoulder in young persons.

The subscapular fascia is a thin membrane attached to the entire circumference of the subscapular fossa, and giving origin by its deep surface to some of the fibres of the Subscapularis.

The Subscapularis (fig. 549) is a large triangular muscle which fills the subscapular fossa, and arises from its medial two-thirds and from the lower two-thirds of the groove on the axillary border of the scapula. Some fibres arise from tendinous laminae which intersect the muscle and are attached to ridges on the bone; others from an aponeurosis, which separates the muscle from the Teres major and the long head of the Triceps brachii. The fibres pass lateralwards, and, gradually converging, end in a tendon which is inserted into the lesser tubercle of the humerus and the front of the capsule of the shoulder-joint. The tendon of the muscle is separated from the neck of the scapula by a large bursa, which communicates with the cavity of the shoulder-joint through an aperture in the articular capsule.

Relations.—The *anterior surface* of this muscle forms a considerable part of the posterior wall of the axilla, and is in relation with the Serratus anterior, Coracobrachialis, and Biceps brachii, the axillary vessels and brachial plexus of nerves, and the subscapular vessels and nerves. Its *posterior surface* is in relation with the scapula and the capsule of the shoulder-joint. Its *lower border* is in contact with the Teres major and Latissimus dorsi.

Nerves.—The Subscapularis is supplied by the fifth and sixth cervical nerves through the subscapular nerves.

Actions.—The Subscapularis rotates the head of the humerus inwards; when the arm is raised, it draws the humerus forwards and downwards. It is a powerful defence to the front of the shoulder-joint.

The fascia supraspinata completes the osseofibrous case in which the Supraspinatus muscle is contained, and its deep surface gives origin to some of the fibres of the muscle. It is thick medially, but thinner laterally under the coraco-acromial ligament.

The **Supraspinatus** (fig. 550) occupies the supraspinatous fossa, arising from its medial two-thirds, and from the fascia supraspinata. The muscular fibres converge to a tendon, which crosses the upper part of the shoulder-joint, and is inserted into the highest of the three impressions on the greater tubercle of the humerus; the tendon is intimately adherent to the capsule of the shoulder-joint.

The **fascia infraspinata** is a dense fibrous membrane, covering the Infraspinatus muscle and fixed to the circumference of the infraspinatus fossa; its deep surface gives origin to some fibres of that muscle. It is intimately attached to the deltoid fascia along the overlapping border of the Deltoides.

FIG. 550.—Muscles on the dorsum of the scapula, and the Triceps brachii.

The **Infraspinatus** (fig. 550) is a thick triangular muscle, which occupies the chief part of the infraspinatous fossa; it arises by fleshy fibres from the medial two-thirds of the fossa, and by tendinous fibres from the ridges on its surface: it also arises from the fascia infraspinata which covers it and separates it from the Teretes major and minor. The fibres converge to a tendon, which glides over the lateral border of the spine of the scapula, and, passing across the posterior part of the capsule of the shoulder-joint, is inserted into the middle impression on the greater tubercle of the humerus. The tendon of this muscle is sometimes separated from the capsule of the shoulder-joint by a bursa which may communicate with the joint-cavity.

The **Teres minor** (fig. 550) is a narrow, elongated muscle, which arises from the dorsal surface of the axillary border of the scapula for the upper two-thirds of its extent, and from two aponeurotic laminae, one of which separates it from the Infraspinatus, the other from the Teres major. Its fibres run obliquely upwards and lateralwards; the upper ones end in a tendon which is inserted into the lowest of the three impressions on the greater tubercle of the humerus; the lower fibres are inserted directly into the humerus immediately below this

impression and just above the origin of the lateral head of the *Triceps brachii*. The tendon of this muscle passes across, and is united with, the posterior part of the capsule of the shoulder-joint.

The **Teres major** (fig. 550) is a thick, somewhat flattened muscle, which arises from the oval area on the dorsal surface of the inferior angle of the scapula, and from the fibrous septa interposed between the muscle and the *Teres minor* and *Infraspinatus*; the fibres are directed upwards and laterally and end in a flat tendon, about 5 cm. long, which is inserted into the crest of the lesser tubercle of the humerus. At its insertion the tendon lies behind that of the *Latissimus dorsi*, from which it is separated by a bursa, the two tendons being, however, united along their lower borders for a short distance.

Nerves.—The *Supraspinatus* and *Infraspinatus* are supplied by the fifth and sixth cervical nerves through the suprascapular nerve; the *Teres minor*, by the fifth cervical, through the axillary nerve; and the *Teres major*, by the fifth and sixth cervical, through the lowest subscapular nerve.

Actions.—The *Supraspinatus* assists the *Deltoides* in raising the arm from the side of the trunk and fixes the head of the humerus in the glenoid cavity. The *Infraspinatus* and *Teres minor* rotate the head of the humerus outwards; they also assist in carrying the arm backwards. One of the most important uses of these three muscles is to protect the shoulder-joint, the *Supraspinatus* supporting it above, and the *Infraspinatus* and *Teres minor* behind. The *Teres major* assists the *Latissimus dorsi* in drawing the previously raised humerus downwards and backwards, and in rotating it inwards; when the arm is fixed it may assist the *Pectorales* and the *Latissimus dorsi* in drawing the trunk forwards.

IV. MUSCLES OF THE ARM

Coracobrachialis.
Biceps brachii.

Brachialis.
Triceps brachii.

The **brachial fascia** or deep fascia of the arm is continuous with that covering the *Deltoides* and the *Pectoralis major*; it forms a thin, loose sheath for the muscles of the arm, and sends septa between them; it is composed of fibres disposed in a circular or spiral direction, and connected together by vertical and oblique fibres. It is thin over the *Biceps brachii*, but thicker where it covers the *Triceps brachii*, and over the epicondyles of the humerus: it is strengthened by fibrous aponeuroses, derived from the *Pectoralis major* and *Latissimus dorsi* medially, and from the *Deltoides* laterally. On either side it gives off a strong intermuscular septum, which is attached to the corresponding supracondylar ridge and epicondyle of the humerus.

The **lateral intermuscular septum** extends from the lower part of the crest of the greater tubercle of the humerus, along the lateral supracondylar ridge, to the epicondyle; it is blended with the tendon of the *Deltoides*, gives attachment to the *Triceps brachii* behind, to the *Brachialis*, *Brachioradialis*, and *Extensor carpi radialis longus* in front, and is perforated by the radial nerve and *arteria profunda brachii*. The **medial intermuscular septum**, thicker than the preceding, extends from the lower part of the crest of the lesser tubercle of the humerus below the *Teres major*, along the medial supracondylar ridge to the epicondyle; it is blended with the tendon of the *Coracobrachialis*, and affords attachment to the *Triceps brachii* behind and the *Brachialis* in front. It is perforated by the ulnar nerve, the superior ulnar collateral artery, and the posterior branch of the inferior ulnar collateral artery.

At the elbow, the deep fascia is attached to the epicondyles of the humerus and the olecranon of the ulna, and is continuous with the deep fascia of the forearm. Just below the middle of the arm, on its medial side, is an oval opening in the deep fascia, which transmits the basilic vein and some lymphatic vessels.

The **Coracobrachialis** (fig. 549) is situated at the upper and medial part of the arm. It arises from the apex of the coracoid process, in common with the tendon of the short head of the *Biceps brachii*, and by muscular fibres from the upper 10 cm. of this tendon; it is inserted by means of a flat tendon into

an impression at the middle of the medial surface and border of the body of the humerus between the origins of the *Triceps brachii* and *Brachialis*.

Relations.—It is perforated by the musculocutaneous nerve, and is in relation, in *front*, with the *Pectoralis major* above, and at its insertion with the brachial vessels and median nerve which cross it; *behind*, with the tendons of the *Subscapularis*, *Latissimus dorsi*, and *Teres major*, the medial head of the *Triceps brachii*, the humerus, and the anterior humeral circumflex vessels; by its *medial border*, with the third part of the axillary artery, the upper part of the brachial artery, the median and musculocutaneous nerves; by its *lateral border*, with the *Biceps brachii* and *Brachialis*.

The ***Biceps brachii*** (fig. 549), a long fusiform muscle placed on the front of the arm, has received its name from the circumstance that it has two heads of origin. The *short head* arises by a thick flattened tendon from the apex of the coracoid process, in common with the *Coracobrachialis*. The *long head* arises by a long narrow tendon from the supraglenoid tuberosity at the upper margin of the glenoid cavity, and is continuous with the glenoidal labrum. This latter tendon, enclosed in a special sheath of the synovial stratum of the articular capsule of the shoulder-joint, arches over the head of the humerus; it emerges from the joint through an opening in the articular capsule close to its humeral attachment and descends in the intertubercular sulcus; it is retained in the sulcus by the transverse humeral ligament and by a fibrous prolongation from the tendon of the *Pectoralis major*. Each tendon is succeeded by an elongated muscular belly, and the two bellies, although closely applied to each other, can be readily separated until within about 7·5 cm. of the elbow-joint. Here they end in a flattened tendon, which is inserted into the rough posterior portion of the tuberosity of the radius, a bursa being interposed between the tendon and the front part of the tuberosity. As the tendon of the muscle approaches the radius it is twisted on itself, so that its anterior surface becomes lateral and is applied to the tuberosity of the radius at its insertion. Opposite the bend of the elbow the tendon gives off, from its medial side, a broad aponeurosis, the *lacertus fibrosus* or *bicipital fascia*, which passes obliquely downwards and medialwards across the brachial artery and is continuous with the deep fascia covering the origins of the *Flexor* muscles of the forearm (fig. 548).

A third head to the *Biceps brachii* is occasionally found, arising at the upper and medial part of the *Brachialis*, with which it is blended, and inserted into the *lacertus fibrosus* and medial side of the tendon of the muscle; in most cases this additional slip lies behind the brachial artery. In some instances the third head consists of two slips, which pass down, one in front of, the other behind the artery.

Relations.—The *Biceps brachii* is overlapped above by the *Pectoralis major* and *Deltoides*; in the rest of its extent it is covered by the fasciæ and skin. Above, it rests on the shoulder-joint and upper part of the humerus; below, it lies on the *Brachialis*, the musculocutaneous nerve, and the *Supinator*. Its *medial border* is in relation with the *Coracobrachialis*, and overlaps the brachial vessels and median nerve; its *lateral border*, with the *Deltoides* and *Brachioradialis*.

The ***Brachialis*** (*Brachialis anticus*) (fig. 549) covers the front of the elbow-joint and the lower half of the humerus. It arises from the lower half of the front of the humerus, commencing above at the insertion of the *Deltoides*, which it embraces by two angular processes, and extending below to within 2·5 cm. of the margin of the articular surface. It also arises from the intermuscular septa, but more extensively from the medial than the lateral; it is separated from the lower part of the lateral intermuscular septum by the *Brachioradialis* and *Extensor carpi radialis longus*. Its fibres converge to a thick tendon, which is inserted into the tuberosity of the ulna and the rough depression on the anterior surface of the coronoid process.

Relations.—It is in relation, in *front*, with the *Biceps brachii*, the brachial vessels, musculocutaneous and median nerves; *behind*, with the humerus and articular capsule of the elbow-joint; by its *medial border*, with the *Pronator teres*, and with the medial intermuscular septum which separates it from the *Triceps brachii* and the ulnar nerve; by its *lateral border*, with the radial nerve, radial recurrent artery, the *Brachioradialis*, and *Extensor carpi radialis longus*.

Nerves.—The *Coracobrachialis*, *Biceps brachii*, and *Brachialis* are supplied by the musculocutaneous nerve; the *Brachialis* usually receives an additional filament

from the radial nerve. The Coracobrachialis receives its supply primarily from the seventh cervical, the Biceps brachii and Brachialis from the fifth and sixth cervical nerves.

Actions.—The Coracobrachialis draws the humerus forwards and medialwards and at the same time assists in retaining the head of the bone in contact with the glenoid cavity. The Biceps brachii is a flexor of the elbow and, to a less extent, of the shoulder: it is also a powerful supinator of the radius and serves to render tense the deep fascia of the forearm by means of the lacertus fibrosus. The Brachialis is a flexor of the forearm, and forms an important defence to the elbow-joint. When the forearm is fixed, the Biceps brachii and Brachialis flex the arm upon the forearm, as in efforts of climbing.

Applied Anatomy.—The long tendon of the Biceps brachii is sometimes dislocated from the intertubercular sulcus. When this occurs, the arm is fixed in a position of abduction, but the head of the humerus can be felt in its proper position. The tendon can generally be replaced by flexing the forearm on the arm and rotating the limb. Rupture of the long tendon of the Biceps brachii may also take place.

The **Triceps brachii** (fig. 550), situated on the back of the arm, is of large size, and arises by three heads (long, lateral, and medial), hence its name.

The *long head* arises by a flattened tendon from the infraglenoid tuberosity of the scapula, being blended at its upper part with the capsule of the shoulder-joint; the muscular fibres pass downwards between the other two heads of the muscle, and join with them in the tendon of insertion.

The *lateral head* has a narrow origin from the posterior surface of the body of the humerus, extending from the insertion of the Teres minor to the upper part of the sulcus for the radial nerve, and from the lateral border of the humerus and the lateral intermuscular septum; the fibres from this origin converge towards the tendon of insertion.

The *medial head* arises from the posterior surface of the body of the humerus, below the sulcus for the radial nerve; it is narrow and pointed above, and extends from the insertion of the Teres major to within 2.5 cm. of the trochlea humeri; it also arises from the medial border of the bone and from the back of the whole length of the medial intermuscular septum. Some of the fibres are directed downwards to the olecranon, while others converge to the tendon of insertion.

The *tendon* of insertion of the Triceps brachii begins about the middle of the muscle: it consists of two aponeurotic laminae, one of which covers the back of the lower half of the muscle; the other is more deeply seated in the substance of the muscle. After receiving the attachment of the muscular fibres, the two lamellae join together above the elbow, and are inserted, for the most part, into the posterior portion of the upper surface of the olecranon; a band of fibres is, however, continued downwards, on the lateral side, over the Anconæus, to blend with the deep fascia of the forearm.

The long head of the Triceps brachii descends between the Teres minor and Teres major, dividing the triangular space between these two muscles and the humerus into two smaller spaces, one triangular, the other quadrangular (fig. 550). The triangular space contains the scapular circumflex vessels; it is bounded by the Teres minor above, the Teres major below, and the scapular head of the Triceps laterally. The quadrangular space transmits the posterior humeral circumflex vessels and the axillary nerve; it is bounded by the Teres minor and capsule of the shoulder-joint above, the Teres major below, the long head of the Triceps brachii medially, and the humerus laterally.

The *Subanconæus* is the name given to a few fibres which spring from the deep surface of the lower part of the Triceps brachii, and are inserted into the posterior part of the articular capsule of the elbow-joint.

Nerves.—The Triceps brachii is supplied by the seventh and eighth cervical nerves through the radial nerve.

Actions.—The Triceps brachii is the great extensor muscle of the forearm, and is the direct antagonist of the Biceps brachii and Brachialis. When the arm is extended, the long head of the muscle may assist the Teres major and Latissimus dorsi in drawing the humerus backwards and in adducting it to the thorax. The

long head supports the under part of the shoulder-joint. The Subanconæus draws up the posterior part of the articular capsule of the elbow-joint during extension of the forearm.

Applied Anatomy.—The insertion of the Triceps brachii into the deep fascia of the forearm is of importance in the operation of excision of the elbow, and should always be carefully preserved. By means of it the patient is enabled to extend the forearm, a movement which would otherwise be accomplished mainly by gravity—that is to say, by allowing the forearm to drop by its own weight.

V. MUSCLES OF THE FOREARM

The **antibrachial fascia** (deep fascia of the forearm), continuous above with the brachial fascia, is a dense investment, which forms a general sheath for the muscles in this region; it is attached, behind, to the olecranon and dorsal border of the ulna, and gives off from its deep surface numerous inter-muscular septa. It gives origin to muscular fibres, especially at the upper part of the medial and lateral sides of the forearm, and forms the boundaries of a series of cone-shaped cavities, in which the muscles are contained; transverse septa are given off both on the volar and dorsal surfaces of the forearm, separating the deep from the superficial layers of muscles. It is much thicker on the dorsal than on the volar surface, and at the lower than at the upper part of the forearm, and is strengthened above by tendinous fibres derived from the Biceps brachii in front, and from the Triceps brachii behind. Over the flexor tendons as they approach the wrist it is especially thickened, and forms the volar carpal ligament. This is continuous with the transverse carpal ligament, and forms a sheath for the tendon of the Palmaris longus which passes over the transverse carpal ligament to be inserted into the palmar aponeurosis. Behind, near the wrist-joint, it is thickened by the addition of many transverse fibres, and forms the dorsal carpal ligament. Apertures exist in the fascia for the passage of vessels and nerves; one of these apertures, of large size and situated at the front of the elbow, transmits a communicating branch between the superficial and deep veins.

The antibrachial or forearm muscles consist of a volar and a dorsal group.

1. VOLAR ANTIBRACHIAL MUSCLES

These muscles are divided for convenience of description into two groups, superficial and deep.

(a) *Superficial Group* (fig. 551)

Pronator teres.	Palmaris longus.
Flexor carpi radialis.	Flexor carpi ulnaris.
Flexor digitorum sublimis.	

The muscles of this group take origin from the medial epicondyle of the humerus by a common tendon; they receive additional fibres from the antibrachial fascia near the elbow, and from the septa which pass from this fascia between the individual muscles.

The **Pronator teres** has a humeral and an ulnar head of origin. The *humeral head*, the larger and more superficial, arises immediately above the medial epicondyle, and from the tendon common to the origin of the other muscles; also from the intermuscular septum between it and the Flexor carpi radialis and from the antibrachial fascia. The smaller *ulnar head* arises from the medial side of the coronoid process of the ulna, and joins the humeral head at an acute angle. The median nerve enters the forearm between the two heads of the muscle, and is separated from the ulnar artery by the ulnar head. The muscle passes obliquely across the forearm, and ends in a flat tendon, which is inserted into a rough impression at the middle of the lateral surface of the body of the radius. The lateral border of the muscle forms

the medial boundary of a triangular hollow, which is situated in front of the elbow-joint and contains the brachial artery, median nerve, and tendon of the Biceps brachii.

Applied Anatomy.—This muscle, when suddenly brought into active use, as in the game of lawn-tennis, is apt to be strained, producing slight swelling, tenderness, and pain on putting the muscle into action. This is known as 'lawn-tennis arm.'

The **Flexor carpi radialis** lies on the medial side of the Pronator teres. It arises from the medial epicondyle by the common tendon, from the anti-brachial fascia, and from the intermuscular septa between it and the adjacent muscles. Slender and aponeurotic in structure at its commencement, it increases in size, and ends in a long tendon which passes through a canal in the lateral part of the transverse carpal ligament and through a groove on the greater multangular bone; the groove is converted into a canal by fibrous tissue and lined by a mucous sheath. The tendon is inserted into the base of the second metacarpal bone, and sends a slip to the base of the third metacarpal bone. In the lower part of the forearm the radial artery lies between the tendon of this muscle and that of the Brachioradialis.

FIG. 551.—Front of the left forearm. Superficial muscles.

The **Palmaris longus** is a slender, fusiform muscle, lying on the medial side of the Flexor carpi radialis. It arises from the medial epicondyle of the humerus by the common tendon, from the intermuscular septa between it and the adjacent muscles, and from the anti-brachial fascia. It ends in a long slender tendon which passes over the upper part of the transverse carpal ligament and is inserted into the anterior surface of the lower half of this ligament and into the central part of the palmar aponeurosis, frequently sending a tendinous slip to the short muscles of the thumb. Just above the wrist, the median nerve lies deep to the tendon.

This muscle is often absent, and is subject to very considerable variations: it may be tendinous above and muscular below, or muscular in the centre with a tendon above and below; or it may consist of two muscular bundles with a central tendon; or finally it may consist solely of a tendinous band.

The **Flexor carpi ulnaris** lies along the ulnar side of the forearm. It arises by two heads, humeral and ulnar, connected by a tendinous arch, beneath which the ulnar nerve passes downwards and the posterior ulnar recurrent artery upwards. The *humeral head* is very small and arises from the medial epicondyle of the humerus by the common tendon; the *ulnar head* arises from the medial margin of the olecranon and from the upper two-thirds of the dorsal border of the ulna by an aponeurosis common to it and the Extensor carpi ulnaris and Flexor digitorum profundus; and from

the intermuscular septum between it and the Flexor digitorum sublimis. The fibres end in a tendon, which occupies the anterior part of the lower half of the muscle and is inserted into the pisiform bone, whence it is prolonged to the hamate and fifth metacarpal bones by the pisohamate and pisometacarpal

ligaments; it is also attached by a few fibres to the transverse carpal ligament. The ulnar vessels and nerve lie on the lateral side of the tendon of insertion of this muscle.

The **Flexor digitorum sublimis** is dorsal to the preceding muscle; it is the largest of the muscles of the superficial group, and arises by two heads, humero-ulnar and radial. The *humero-ulnar head* arises from the medial epicondyle of the humerus by the common tendon, from the ulnar collateral ligament of the elbow-joint, from the intermuscular septa between it and the preceding muscles, and from the medial side of the coronoid process, above the ulnar origin of the Pronator teres. The *radial head*, a thin sheet of muscle, arises from the oblique line of the radius, extending from the radial tuberosity to the insertion of the Pronator teres. The muscle speedily separates into two planes of muscular fibres, superficial and deep: the superficial plane divides into two parts which end in tendons for the middle and ring fingers; the deep plane gives off a muscular slip to join that part of the superficial plane which is associated with the tendon of the ring finger, and then divides into two parts, which end in tendons for the index and little fingers. As the four tendons pass beneath the transverse carpal ligament into the palm of the hand, they are arranged in pairs, the superficial pair going to the middle and ring fingers, the deep pair to the index and little fingers. The tendons diverge from one another in the palm and form deep relations to the superficial volar arch and digital branches of the median and ulnar nerves. Opposite the bases of the first phalanges each tendon divides into two slips, to allow of the passage of the corresponding tendon of the Flexor digitorum profundus; the two slips then reunite and form a grooved channel for the reception of the accompanying tendon of the Flexor digitorum profundus. Finally the tendon divides and is inserted into the sides of the second phalanx about its middle.

(b) *Deep Group* (fig. 552)

Flexor digitorum profundus.

Flexor pollicis longus.

Pronator quadratus.

The **Flexor digitorum profundus** is situated on the ulnar side of the forearm, dorsal to the superficial flexors. It arises from the upper three-fourths of the volar and medial surfaces of the body of the ulna, embracing the insertion of the Brachialis above, and extending below to within a short distance of the Pronator quadratus. It also arises from a depression on the medial side of the coronoid process; by an aponeurosis from the upper three-fourths of the dorsal border of the ulna, in common with the Flexor and Extensor carpi ulnaris; and from the ulnar half of the interosseous membrane. The muscle ends in four tendons which run behind the transverse carpal ligament, dorsal to the tendons of the Flexor digitorum sublimis. The portion of the muscle for the index finger is usually distinct throughout, but the tendons for the middle, ring, and little fingers are connected together by areolar tissue and tendinous slips, as far as the palm of the hand. Opposite the first phalanges the tendons pass through the openings in the tendons of the Flexor digitorum sublimis, and are inserted into the bases of the last phalanges.

Four small muscles, the Lumbricales, are connected with the tendons of the Flexor digitorum profundus in the palm. They will be described with the muscles of the hand (p. 508).

Fibrous sheaths of the flexor tendons.—After leaving the palm, the tendons of the Flexores digitorum sublimis and profundus lie in osseo-aponeurotic canals (fig. 563, p. 507), formed behind by the phalanges and in front by fibrous bands, which arch across the tendons, and are attached on either side to the margins of the phalanges and to the volar accessory ligaments of the interphalangeal joints. Opposite the middle of the proximal and second phalanges the bands (*digital vaginal ligaments*) are very strong, and the fibres are transverse; but opposite the joints they are much thinner, and consist of *annular* and *cruciate* fibres. Each canal is lined by a mucous sheath, which is reflected on the contained tendons.

As the flexor tendons approach their insertions they are connected to the dorsal parts of the enclosing sheaths by triangular and thread-like bands

MYOLOGY

FIG. 552.—Front of the left forearm.
Deep muscles.

of the mucous sheaths. These bands, termed *vincula tendinea* (fig. 553), convey minute vessels to the tendons, and are of two kinds, (a) *vincula brevia* and (b) *vincula longa*.

The *vincula brevia*, two in number in each finger, are triangular bands attached to the deep surfaces of the tendons close to their insertions; one connects the tendon of the Flexor digitorum sublimis to the front of the first interphalangeal joint and adjacent part of the first phalanx, and the other the tendon of the Flexor digitorum profundus to the front of the second interphalangeal joint and adjacent part of the second phalanx. The *vincula longa* are thread-like slips, of which two are usually attached to each tendon of the Flexor digitorum sublimis, and one to each tendon of the Flexor digitorum profundus. Those of the Flexor digitorum sublimis are connected to the slips of that tendon where these fold over the tendon of the Flexor digitorum profundus, and, passing one on either side of the latter tendon, are attached to the sheath at the lateral margins of the proximal third of the first phalanx. That of the tendon of the Flexor digitorum profundus is fixed to its tendon shortly after the latter has pierced the tendon of the Flexor digitorum sublimis. It runs upwards and backwards, perforates one of the two slips of the latter tendon, or passes between the two slips; thereafter it blends with the vinculum breve of the Flexor digitorum sublimis, and is attached to the sheath at the distal end of the first phalanx.

The Flexor pollicis longus is situated on the radial side of the forearm in the same plane as the Flexor digitorum profundus. It arises from the grooved volar surface of the body of the radius, extending from immediately below the tuberosity and oblique line, to within a short distance of the Pronator quadratus. It arises also from the adjacent part of the interosseous membrane, and generally by a fusiform fleshy slip

from the medial border of the coronoid process below the Flexor digitorum sublimis and Pronator teres, or from the medial epicondyle of the humerus. The fibres end in a flattened tendon, which passes behind the transverse carpal ligament, is then lodged between the lateral head of the Flexor pollicis brevis and the oblique part of the Adductor pollicis, and, entering an osseo-aponeurotic canal similar to those for the flexor tendons of the fingers, is inserted into the base of the distal phalanx of the thumb. The volar interosseous nerve and vessels descend on the front of the interosseous membrane between the Flexor pollicis longus and Flexor digitorum profundus.

The **Pronator quadratus** is a flat, quadrilateral muscle, extending across the front of the lower parts of the radius and ulna. It arises from the pronator

FIG. 553.—Tendons of forefinger, and vincula tendinea.

ridge on the lower part of the volar surface of the body of the ulna; from the medial part of the volar surface of the lower fourth of the ulna; and from a strong aponeurosis which covers the medial third of the muscle. The fibres pass lateralwards and slightly downwards, to be inserted into the lower fourth of the lateral border and the volar surface of the body of the radius; the deeper fibres are inserted into the triangular area above the ulnar notch of the radius.

Nerves.—All the muscles of the superficial layer are supplied by the median nerve, excepting the Flexor carpi ulnaris, which is supplied by the ulnar. The Pronator teres, the Flexor carpi radialis, and the Palmaris longus derive their supply primarily from the sixth cervical nerve; the Flexor digitorum sublimis from the seventh and eighth cervical and first thoracic nerves, and the Flexor carpi ulnaris from the eighth cervical and first thoracic. Of the deep layer, the Flexor digitorum profundus is supplied by the eighth cervical and first thoracic through

the ulnar nerve, and the volar interosseous branch of the median nerve. The *Flexor pollicis longus* and *Pronator quadratus* are supplied by the eighth cervical and first thoracic through the volar interosseous branch of the median nerve.

Actions.—These muscles act upon the forearm, wrist, and hand. The *Pronator teres* and *Pronator quadratus* rotate the radius upon the ulna, rendering the hand prone. The *Flexor carpi radialis* is a flexor and abductor of the wrist; it also assists in pronating the hand. The *Flexor carpi ulnaris* is a flexor and adductor of the wrist. The *Palmaris longus* tightens the palmar aponeurosis and flexes the wrist. All these muscles may assist in flexing the elbow. The *Flexor digitorum sublimis* flexes first the middle, and then the proximal, phalanges; it also assists in flexing the wrist and elbow. After the *Flexor sublimis* has bent the second phalanges, the *Flexor profundus* flexes the terminal ones; it also assists in flexing the wrist. The *Flexor pollicis longus* is a flexor of the phalanges of the thumb; it may assist in flexing the wrist.

2. DORSAL ANTIBRACHIAL MUSCLES

These muscles are divided for convenience of description into two groups, superficial and deep.

(a) *Superficial Group* (fig. 554)

<i>Brachioradialis.</i>	<i>Extensor digitorum communis.</i>
<i>Extensor carpi radialis longus.</i>	<i>Extensor digiti quinti proprius.</i>
<i>Extensor carpi radialis brevis.</i>	<i>Extensor carpi ulnaris.</i>
<i>Anconæus.</i>	

The ***Brachioradialis*** (*Supinator longus*) is the most superficial muscle on the radial side of the forearm. It arises from the upper two-thirds of the lateral supracondylar ridge of the humerus, and from the lateral intermuscular septum. Interposed between it and the *Brachialis* are the radial nerve and the anastomosis between the *arteria profunda brachii* and the radial recurrent artery. The fibres end above the middle of the forearm in a flat tendon which is inserted into the lateral side of the base of the styloid process of the radius. The tendon is crossed near its insertion by the tendons of the *Abductor pollicis longus* and *Extensor pollicis brevis*; on its ulnar side is the radial artery.

The ***Extensor carpi radialis longus*** is partly covered by the *Brachioradialis*. It arises mainly from the lower third of the lateral supracondylar ridge of the humerus and from the lateral intermuscular septum, but it receives a few fibres from the common tendon of origin of the *Extensor* muscles of the forearm. The muscle ends at the upper third of the forearm in a flat tendon, which runs along the lateral border of the radius, deep to the *Abductor pollicis longus* and *Extensor pollicis brevis*; it then passes under cover of the dorsal carpal ligament, where it lies in a groove on the back of the radius common to it and the *Extensor carpi radialis brevis*, immediately behind the styloid process. It is inserted into the dorsal surface of the base of the second metacarpal bone, on its radial side.

The ***Extensor carpi radialis brevis*** is shorter than the preceding muscle and is covered by it. It arises from the lateral epicondyle of the humerus, by a tendon common to it and the next three muscles; from the radial collateral ligament of the elbow-joint; from a strong aponeurosis which covers its surface; and from the intermuscular septa between it and the adjacent muscles. The fibres end about the middle of the forearm in a flat tendon, which closely accompanies that of the preceding muscle to the wrist; it passes beneath the *Abductor pollicis longus* and *Extensor pollicis brevis*, then under cover of the dorsal carpal ligament, and is inserted into the dorsal surface of the base of the third metacarpal bone on its radial side and distal to the styloid process. Under the dorsal carpal ligament the tendon lies on the back of the radius in a shallow groove, to the ulnar side of the groove which lodges the tendon of the *Extensor carpi radialis longus*, and separated from it by a faint ridge.

The tendons of the two preceding muscles pass through the same compartment of the dorsal carpal ligament in a single mucous sheath.

The *Extensor digitorum communis* arises from the lateral epicondyle of the humerus, by the common tendon; from the intermuscular septa between it and the adjacent muscles, and from the antibrachial fascia. It divides below into four tendons, which pass, together with that of the *Extensor indicis proprius*, through a compartment of the dorsal carpal ligament, within a mucous sheath. The tendons then diverge on the back of the hand, and are inserted into the second and third phalanges of the fingers in the following manner. Opposite the metacarpophalangeal articulation each tendon is bound by fasciculi to the collateral ligaments and serves as the dorsal ligament of this joint; after crossing the joint, it spreads out into a broad aponeurosis, which covers the dorsal surface of the first phalanx and is there reinforced by the corresponding tendons of the *Interossei* and *Lumbricalis*. Opposite the first interphalangeal joint this aponeurosis divides into three slips, an intermediate and two collateral: the intermediate is inserted into the base of the second phalanx; the two collateral are continued onwards along the sides of the second phalanx, and uniting by their contiguous margins, are inserted into the dorsal surface of the unguis phalanx. As the tendons cross the interphalangeal joints, they furnish them with dorsal ligaments. The tendon to the index finger is accompanied by the *Extensor indicis proprius*, which lies on its ulnar side. On the back of the hand, the tendons to the middle, ring, and little fingers are connected by two obliquely placed bands, one from the third tendon passing distalwards and lateralwards to the second tendon, and the other passing from the fourth tendon to the third. Occasionally the second tendon is connected to the first by a thin oblique band.

The *Extensor digiti quinti proprius* is a slender muscle placed medially to, and usually connected with, the *Extensor digitorum communis*. It arises

Fig. 554.—Posterior surface of the forearm. Superficial muscles.

from the common Extensor tendon by a thin tendinous slip, and from the inter-muscular septa between it and the adjacent muscles. Its tendon runs through

FIG. 555.—Posterior surface of the forearm.
Deep muscles.

a compartment of the dorsal carpal ligament behind the distal radio-ulnar joint, then divides into two as it crosses the hand, and finally joins the expansion of the Extensor digitorum communis tendon on the dorsum of the first phalanx of the fifth digit.

The **Extensor carpi ulnaris** lies on the ulnar side of the forearm. It arises from the lateral epicondyle of the humerus, by the common extensor tendon; from the dorsal border of the ulna by an aponeurosis in common with the **Flexor carpi ulnaris** and the **Flexor digitorum profundus**; and from the antibrachial fascia. It ends in a tendon, which runs in a groove between the head and the styloid process of the ulna, passing through a separate compartment of the dorsal carpal ligament, and is inserted into the tubercle on the ulnar side of the base of the fifth metacarpal bone.

The **Anconæus** is a small triangular muscle on the back of the elbow-joint, and appears to be a continuation of the **Triceps brachii**. It arises by a separate tendon from the posterior part of the lateral epicondyle of the humerus; its fibres diverge and are inserted into the side of the olecranon, and upper fourth of the dorsal surface of the body of the ulna.

(b) *Deep Group* (fig. 555)

Supinator.

Abductor pollicis longus.

Extensor pollicis brevis.

Extensor pollicis longus.

Extensor indicis proprius.

The **Supinator** (**Supinator brevis**) (fig. 556) curves round the upper third of the radius. It consists of fibres arranged in two planes, between which the deep branch of the radial nerve passes. The two planes arise in common—the superficial one by tendinous and the deeper by muscular fibres—from the lateral epicondyle of the humerus; from the radial collateral ligament of the elbow-joint, and the annular ligament of the proximal radio-ulnar

joint; from the ridge on the ulna, which runs obliquely downwards from the dorsal end of the radial notch; from the distal part of the triangular depression below the notch; and from a tendinous expansion which covers the surface of the muscle. The superficial fibres surround the upper part of the radius, and are inserted into the lateral edge of the radial tuberosity and the oblique line of the radius as low down as the insertion of the Pronator teres. The upper fibres of the deeper plane form a sling-like fasciculus, which encircles the neck of the radius above the tuberosity and is attached to the back part of its medial surface: the greater part of this portion of the muscle is inserted into the dorsal and lateral surfaces of the body of the radius, between the oblique line and the head of the bone.

FIG. 558.—The Supinator.

The **Abductor pollicis longus** (*Extensor ossis metacarpi pollicis*) lies immediately below the Supinator and is sometimes united with it. It arises from the lateral part of the dorsal surface of the body of the ulna below the insertion of the Anconæus, from the interosseous membrane, and from the middle third of the dorsal surface of the body of the radius. Passing obliquely downwards and lateralwards, it ends in a tendon, which runs through a groove on the lateral side of the lower end of the radius, accompanied by the tendon of the *Extensor pollicis brevis*, and is inserted into the radial side of the base of the first metacarpal bone. It occasionally gives off two slips near its insertion: one to the greater multangular bone, and the other to blend with the origin of the *Abductor pollicis brevis*.

The **Extensor pollicis brevis** lies on the medial side of, and is closely connected with, the *Abductor pollicis longus*. It arises from the dorsal surface of the body of the radius below that muscle, and from the interosseous membrane. Its direction is similar to that of the *Abductor pollicis longus*, its tendon passing through the same groove on the lateral side of the lower end of the radius, to be inserted into the dorsal aspect of the base of the first phalanx of the thumb.

The **Extensor pollicis longus** is larger than the preceding muscle, the origin of which it partly covers. It arises from the lateral part of the middle third of the dorsal surface of the body of the ulna below the origin of the *Abductor pollicis longus*, and from the interosseous membrane. It ends in a tendon, which passes through a compartment of the dorsal carpal ligament, lying in a narrow, oblique groove on the back of the lower end of the radius. It then crosses obliquely the tendons of the *Extensores carpi radialis longus* and *brevis*, and is separated from the *Extensor brevis pollicis* by a triangular interval, in which the radial artery is found; it is inserted into the base of the last phalanx of the thumb. The radial artery is crossed by the tendons of the *Abductor pollicis longus* and of the *Extensores pollicis longus* and *brevis*.

The *Extensor indicis proprius* is a narrow, elongated muscle, placed medially to, and parallel with, the preceding. It arises from the dorsal surface of the body of the ulna below the origin of the *Extensor pollicis longus*, and from the interosseous membrane. Its tendon passes under cover of the dorsal carpal ligament in the same compartment as that which transmits the tendons of the *Extensor digitorum communis*; opposite the head of the second metacarpal bone it joins the ulnar side of the tendon of the *Extensor digitorum communis* which runs to the index finger.

Nerves.—The *Brachioradialis* is supplied by the fifth and sixth, the *Extensores carpi radialis longus* and *brevis* by the sixth and seventh, and the *Anconæus* by the seventh and eighth cervical nerves, through the radial nerve; the remaining muscles are innervated through the deep radial nerve, the *Supinator* being supplied by the sixth, and the others by the seventh cervical.

Actions.—The *Anconæus* assists the *Triceps* in extending the forearm. The *Brachioradialis* is a flexor of the elbow-joint, but only acts as such when the movement of flexion has been initiated by the *Biceps brachii* and *Brachialis*. The *Supinator* and *Biceps brachii* bring the hand into the supine position. The *Extensor carpi radialis longus* extends the wrist and abducts the hand, and may assist in bending the elbow-joint; at all events it serves to fix or steady this articulation. The *Extensor carpi radialis brevis* extends the wrist, and may also act slightly as an abductor of the hand. The *Extensor carpi ulnaris* extends the wrist, but when acting alone inclines the hand towards the ulnar side: by its continued action it extends the elbow-joint. The *Extensor digitorum communis* extends the phalanges, then the wrist, and finally the elbow. Owing to its attachments to the collateral ligaments of the metacarpophalangeal joints it acts principally on the proximal phalanges, the middle and terminal phalanges being extended mainly by the *Interossei* and *Lumbricales*; it tends to separate the fingers as it extends them. The *Extensor digiti quinti proprius* extends the little finger, and by its continued action assists in extending the wrist; it is owing to this muscle that the little finger can be extended or pointed while the others are flexed. The chief action of the *Abductor pollicis longus* is to carry the thumb lateralwards from the palm of the hand; by its continued action it helps to extend and abduct the wrist. The *Extensor pollicis brevis* extends the proximal phalanx, and the *Extensor pollicis longus* the terminal phalanx of the thumb; they help to extend and abduct the wrist. The *Extensor indicis proprius* extends the index finger, and assists in extending the wrist.

Applied Anatomy.—The tendons of the *Abductor longus* and *Extensors* of the thumb are liable to become strained, and their sheaths inflamed (*tenosynovitis*) after excessive exercise, producing a sausage-shaped swelling along the course of the tendons and giving a peculiar grating sensation to the touch when the muscles are put in action.

Paralysis of the extensor muscles of the wrists and fingers resulting in 'wrist-drop' is common in lead poisoning in painters. The *Brachioradialis* usually escapes, unless the muscles of the upper arm are paralysed also. The different extensor muscles are affected unequally as a rule. Thus the thumb, or index, or little finger may be but slightly implicated, and recover rapidly while the extensors of the other fingers or wrist remain powerless; and some of the flexor muscles of the fingers may become paretic. This apparently selective action of the lead in cases of lead poisoning depends in reality upon occupational overuse of the affected muscles or groups of muscles. Muscular atrophy often follows this lead palsy.

VI. MUSCLES OF THE HAND

The muscles of the hand are subdivided into three groups: 1, those of the thumb, which occupy the radial side and produce the *thenar* eminence; 2, those of the little finger, which occupy the ulnar side and give rise to the *hypothenar* eminence; 3, those in the middle of the palm and between the metacarpal bones.

The volar carpal ligament is the thickened band of antibrachial fascia which extends from the radius to the ulna in front of the *Flexor* tendons as they approach the wrist.

The transverse carpal ligament (anterior annular ligament) (fig. 558, 559) is a strong, fibrous band, which arches over the front of the carpus, converting the deep groove on the front of the carpal bones into a tunnel, through which

the flexor tendons of the digits and the median nerve pass. It is attached, medially, to the pisiform bone and to the hamulus of the hamate bone; laterally, it splits into two laminae, a superficial attached to the tubercles of the navicular and greater multangular bones, and a deep to the posterior lip of the groove

FIG. 557.—Transverse section across distal ends of radius and ulna.

on the latter bone; the two laminae forming with the groove on the greater multangular bone a tunnel which is traversed by the tendon of the Flexor carpi radialis, contained in a special mucous sheath. It is continuous, above, with the volar carpal ligament; and below, with the palmar aponeurosis. It is crossed superficially by the ulnar vessels and nerve, and the cutaneous

FIG. 558.—Transverse section across the wrist.

branches of the median and ulnar nerves. On its volar surface the tendons of the Palmaris longus and Flexor carpi ulnaris are partly inserted; below, it gives origin to the short muscles of the thumb and little finger.

The mucous sheaths of the tendons on the front of the wrist.—Two sheaths envelop the tendons as they pass behind the transverse carpal ligament, one for the Flexores digitorum sublimis and profundus, the other for the Flexor

pollicis longus (fig. 559). They extend into the forearm for about 2.5 cm. above the transverse carpal ligament, and occasionally communicate with each other behind the ligament. The sheath surrounding the Flexores digitorum reaches about halfway along the metacarpal bones, where it ends in blind diverticula

FIG. 559.—The mucous sheaths of the tendons on the front of the wrist and digits.

around the tendons to the index, middle, and ring fingers. It is prolonged on the tendons to the little finger and usually communicates with the digital mucous sheath of these tendons. The sheath of the tendon of the Flexor pollicis longus is continued along the thumb as far as the insertion of the tendon. The mucous sheaths enveloping the terminal parts of the tendons of the Flexores digitorum have been described on pp. 493, 494.

The dorsal carpal ligament (posterior annular ligament) (fig. 560) is a strong, fibrous band, extending obliquely downwards and medialwards across the back of the wrist, and consisting of part of the antibrachial fascia, strengthened by the addition of some transverse fibres. It is attached, medially,

FIG. 560.—The mucous sheaths of the tendons on the back of the wrist.

to the styloid process of the ulna and to the triquetral and pisiform bones; laterally, to the lateral margin of the radius; and, in its passage across the wrist, to the ridges on the dorsal surface of the radius.

The mucous sheaths of the tendons on the back of the wrist.—Between the dorsal carpal ligament and the bones six compartments are formed for the passage of tendons, each compartment containing a mucous sheath.

One is found in each of the following positions (fig. 560) : (1) on the lateral side of the styloid process, for the tendons of the Abductor pollicis longus and Extensor pollicis brevis ; (2) behind the styloid process, for the tendons of the Extensores carpi radialis longus and brevis ; (3) about the middle of the dorsal surface of the radius, for the tendon of the Extensor pollicis longus ; (4) to the medial side of the latter, for the tendons of the Extensor digitorum communis and Extensor indicis proprius ; (5) opposite the interval between the radius and ulna, for the Extensor digiti quinti proprius ; (6) between the head and styloid processes of the ulna, for the tendon of the Extensor carpi ulnaris.

FIG. 561.—The palmar aponeurosis.

The sheaths lining these compartments extend from above the dorsal carpal ligament ; those for the tendons of Abductor pollicis longus, Extensor pollicis brevis, Extensores carpi radiales, and Extensor carpi ulnaris stop immediately proximal to the bases of the metacarpal bones, while the sheaths for Extensor digitorum communis, Extensor indicis proprius, and Extensor digiti quinti proprius are prolonged to the junction of the proximal with the intermediate third of the metacarpus.

The **palmar aponeurosis** (fig. 561) invests the muscles of the palm, and consists of central, lateral, and medial portions.

The *central portion* occupies the middle of the palm, is triangular in shape, and of great strength and thickness. Its apex is continuous with the lower margin of the transverse carpal ligament, and gives insertion to the expanded tendon of the Palmaris longus. Its base divides below into four slips, one for

each finger. Each slip gives off superficial fibres to the skin of the palm and finger, those to the palm joining the skin at the furrow corresponding to the metacarpophalangeal articulations, and those to the fingers passing into the skin at the transverse folds at the bases of the fingers. The deeper part of each slip subdivides into two processes, which are inserted into the fibrous sheaths of the flexor tendons; from the sides of these processes offsets are attached to the transverse metacarpal ligament. By this arrangement short channels are formed on the front of the heads of the metacarpal bones; through these the flexor tendons pass. The intervals between the four slips transmit the digital vessels and nerves, and the tendons of the Lumbricales. At the points of division into the slips mentioned, numerous strong, transverse fibres bind the separate processes together. The central part of the palmar aponeurosis is intimately bound to the skin by dense fibro-areolar tissue, and gives origin by its medial margin to the *Palmaris brevis*. It covers the superficial volar arch, the tendons of the Flexor digitorum muscles, the terminal part of the median nerve, and the superficial part of the ulnar nerve; on either side it gives off a septum which separates the intermediate from the lateral and medial groups of muscles.

The *lateral and medial portions* of the palmar aponeurosis are thin, fibrous layers, which cover the muscles of the ball of the thumb, and the muscles of the little finger respectively; they are continuous with the central portion and with the fascia on the dorsum of the hand.

The *superficial transverse fasciculi* form a thin band (fig. 561) which stretches across the roots of the fingers, and is attached to the skin of the clefts, and medially to the fifth metacarpal bone, forming a sort of rudimentary web. The digital vessels and nerves pass beneath these fasciculi.

Applied Anatomy.—The palmar aponeurosis is liable to undergo contraction, producing a very inconvenient deformity, known as ‘Dupuytren’s contraction.’ The ring and little fingers are most frequently implicated, but the others may also be involved. The proximal phalanx is flexed and cannot be straightened, and the two distal phalanges become similarly flexed as the disease advances.

Owing to their constant exposure to injury and septic influences, the fingers are very liable to become the seat of serious inflammatory mischief. To this inflammation the term *paronychia* or *whitlow* is given, and the affection may assume various degrees of severity. In the mildest cases the disease is confined to the superficial layer of the skin, and suppuration takes place beneath it. This is known as *subcuticular paronychia*, and is a comparatively simple condition, for an incision through the epidermis will at once relieve it. The only complication is that the pus may burrow under the nail, causing increased pain. A more severe condition is the *paronychia cellulosa*, in which the pulp of the end of the finger is involved. This is attended with intense throbbing pain, owing to the fact that the inflamed area is covered by thick and often horny epithelium, especially when the disease occurs in the labouring classes, as it so frequently does. In these cases, unless a timely incision is made, the inflammation is liable to involve the periosteum covering the phalanx, and *subperiosteal paronychia* is set up, which is followed by necrosis of a part or the whole of the ungual phalanx. In other cases, the inflammation may involve the theca of the flexor tendons, and a *thecal paronychia* may result. The inflammation then rapidly spreads up the sheath: but the extent will depend upon the particular digit involved. From the description of the flexor sheaths given above, it will be evident that inflammation of the mucous sheaths of the thumb and little finger may prove a far more formidable affection than that of the other three digits, because the sheaths of these two digits communicate with the large mucous sheath which surrounds the flexor tendons (pp. 501, 502), and the inflammation may extend into the palm of the hand and behind the transverse carpal ligament into the forearm.

In order to relieve these conditions, free and early incisions are necessary, and must be made with discrimination, in order to avoid wounding important structures. In the pulp of the finger—i.e. over the distal phalanx—the incision should be made in the middle line and down to the bone. In the rest of the finger, the incision should be made in the middle line over the phalanges, and not over the interphalangeal joints. In the palm of the hand, incisions may be made either on the distal or proximal side of the superficial volar arch. On the distal side the incisions should be made over the metacarpal bones, preferably those of the index and middle finger. On the proximal side, the safest line of incision is along the radial side of the hypothenar eminence, between the ulnar artery and nerve medially, and the median nerve laterally. When suppuration has extended under the transverse carpal ligament, and incisions are required in the forearm, the positions in which they should be made are over the tendons of the Flexor digitorum sublimis, between the median nerve and the ulnar artery, and over the tendon of the Flexor pollicis longus, between the radial artery and the tendon of the Flexor carpi radialis.

Chronic inflammation of the common flexor sheath is occasionally met with, constituting a disease known as *compound palmar ganglion*; it presents an hour-glass outline, with a swelling in front of the wrist and another in the palm of the hand, and a constriction, corresponding to the transverse carpal ligament, between the two. The fluid can be forced from the one swelling to the other under the ligament, and when this is done, a creaking sensation is sometimes perceived, from the presence of 'melon-seed' bodies in the interior of the ganglion.

1. LATERAL VOLAR MUSCLES (figs. 562, 563)

Abductor pollicis brevis.
Opponens pollicis.

Flexor pollicis brevis.
Adductor pollicis.

The **Abductor pollicis brevis** is a thin, subcutaneous muscle; it arises from the transverse carpal ligament, the tuberosity of the navicular bone, and the ridge of the greater multangular bone. Running lateralwards and downwards, it is inserted by a thin, flat tendon into the radial side of the base of the

FIG. 562.—The Opponens pollicis, Adductor pollicis and Opponens digiti quinti muscles.

first phalanx of the thumb and the capsule of the metacarpophalangeal articulation.

The **Opponens pollicis** is placed beneath the preceding. It arises from the ridge on the greater multangular bone, and from the transverse carpal ligament, passes downwards and lateralwards, and is inserted into the whole length of the metacarpal bone of the thumb on its radial side.

The **Flexor pollicis brevis** consists of two portions, superficial and deep. The *superficial portion* arises from the lower border of the transverse carpal ligament and the lower part of the ridge on the greater multangular bone; it passes along the radial side of the tendon of the Flexor pollicis longus, and is inserted into the radial side of the base of the first phalanx of the thumb; in its tendon of insertion there is a sesamoid bone. The *deep portion* is very small. It arises from the ulnar side of the base of the first metacarpal bone and is inserted into the ulnar side of the base of the first phalanx with the oblique part of the Adductor pollicis; it is sometimes described as the *first volar interosseous muscle*.

The **Adductor pollicis** consists of an oblique and a transverse part. The *oblique part* arises from the capitate and lesser multangular bones, the bases

of the second and third metacarpal bones, the intercarpal ligaments, and the sheath of the tendon of the Flexor carpi radialis. Most of its fibres converge to a tendon, which, uniting with the tendons of the deep portion of the Flexor pollicis brevis and the transverse part of the Adductor, is inserted into the

FIG. 563.—The muscles of the left hand. Palmar surface.

ulnar side of the base of the first phalanx of the thumb, a sesamoid bone being present in the tendon. A considerable fasciculus, however, passes beneath the tendon of the Flexor pollicis longus and joins the superficial portion of the Flexor brevis and the Abductor pollicis brevis. The *transverse part* (fig. 562) is the most deeply seated of this group of muscles. It is of a triangular form, and arises from the distal two-thirds of the volar surface of the third metacarpal

bone ; the fibres converge, to be inserted with the oblique part of the muscle and with the deep part of the *Flexor pollicis brevis* into the ulnar side of the base of the first phalanx of the thumb.

Nerves.—The *Abductor pollicis brevis*, *Opponens pollicis*, and superficial portion of the *Flexor pollicis brevis* are supplied by the sixth and seventh cervical nerves through the median nerve ; the *Adductor* and the deep portion of the *Flexor pollicis brevis*, by the eighth cervical nerve through the ulnar nerve.

Actions.—The *Abductor pollicis brevis* draws the thumb forwards in a plane at right angles to that of the palm of the hand and abducts the proximal phalanx. The *Adductor pollicis* is the opponent of this muscle, and approximates the thumb to the palm. The *Opponens pollicis* flexes the metacarpal bone, i.e. draws it medialwards over the palm ; the *Flexor pollicis brevis* flexes and adducts the proximal phalanx.

2. MEDIAL VOLAR MUSCLES (figs. 562, 563)

Palmaris brevis.
Abductor digiti quinti.

Flexor digiti quinti brevis.
Opponens digiti quinti.

The *Palmaris brevis* is a thin, quadrilateral muscle, placed beneath the skin of the ulnar side of the hand. It arises by tendinous fasciculi from the transverse carpal ligament and palmar aponeurosis ; the fleshy fibres are inserted into the skin on the proximal part of the ulnar border of the hand.

The *Abductor digiti quinti* is situated on the ulnar border of the palm of the hand. It arises from the pisiform bone and from the tendon of the *Flexor carpi ulnaris*, and ends in a flat tendon which divides into two slips ; one is inserted into the ulnar side of the base of the first phalanx of the little finger, the other into the ulnar border of the aponeurosis of the *Extensor digiti quinti proprius*.

The *Flexor digiti quinti brevis* lies on the radial side of the preceding muscle. It arises from the convex surface of the hamulus of the hamate bone and the volar surface of the transverse carpal ligament, and is inserted into the ulnar side of the base of the first phalanx of the little finger. It is separated from the *Abductor* by the deep branches of the ulnar artery and nerve. This muscle is sometimes wanting ; the *Abductor* is then, usually, of large size.

The *Opponens digiti quinti* (fig. 562) is of a triangular form, and placed under cover of the *Flexor* and *Abductor*. It arises from the convexity of the hamulus of the hamate bone, and contiguous portion of the transverse carpal ligament ; it is inserted into the whole length of the ulnar margin of the fifth metacarpal bone.

Nerves.—All the muscles of this group are supplied by the eighth cervical nerve through the ulnar nerve.

Actions.—The *Palmaris brevis* corrugates the skin on the ulnar side of the palm. The *Abductor* and *Flexor digiti quinti brevis* abduct the little finger and assist in flexing its proximal phalanx. The *Opponens digiti quinti* draws forwards the fifth metacarpal bone, so as to deepen the hollow of the palm.

3. INTERMEDIATE MUSCLES

Lumbricales.

Interossei.

The *Lumbricales* (fig. 563) are four small fleshy fasciculi, which take origin from the tendons of the *Flexor digitorum profundus*. The first and second arise from the radial sides and volar surfaces of the tendons of the index and middle fingers respectively ; the third, from the contiguous sides of the tendons of the middle and ring fingers ; and the fourth, from the contiguous sides of the tendons of the ring and little fingers. Each passes to the radial side of the corresponding finger, and opposite the metacarpophalangeal articulation is inserted into the tendinous expansion of the *Extensor digitorum communis* covering the dorsal aspect of the finger.

The *Interossei* (figs. 564, 565) occupy the intervals between the metacarpal bones, and are divided into a dorsal and a volar set.

The *Interossei dorsales*, four in number, are bipennate muscles, each arising by two heads from the adjacent sides of the metacarpal bones, but more extensively from the metacarpal bone of the finger into which the muscle is inserted. They are inserted into the bases of the first phalanges and into the aponeuroses of the tendons of the *Extensor digitorum communis*. Between the double origin of each of these muscles is a narrow triangular interval; through the first of these intervals the radial artery passes; through each of the others a perforating branch from the deep volar arch is transmitted. The *first* or *Abductor indicis* is larger than the others; it is inserted into the radial side of the index finger. The *second* and *third* are inserted into the middle finger, the former into its radial, the latter into its ulnar side. The *fourth* is inserted into the ulnar side of the ring finger.

The *Interossei volares*, three in number, are smaller than the *Interossei dorsales*, and are placed upon the volar surfaces of the metacarpal bones, rather than between them. Each arises from the entire length of the metacarpal bone

FIG. 564.—The *Interossei dorsales* of left hand.

FIG. 565.—The *Interossei volares* of left hand.

of one finger, and is inserted into the side of the base of the first phalanx of the same finger, and into the aponeurotic expansion of the *Extensor communis digitorum* tendon.

The *first* arises from the ulnar side of the second metacarpal bone, and is inserted into the same side of the first phalanx of the index finger. The *second* arises from the radial side of the fourth metacarpal bone, and is inserted into the same side of the ring finger. The *third* arises from the radial side of the fifth metacarpal bone, and is inserted into the same side of the little finger. From this account it may be seen that each finger is provided with a pair of *Interossei*, with the exception of the little finger, in which the *Abductor* takes the place of one of the pair.

As already mentioned (p. 506), the deep head of *Flexor pollicis brevis* is sometimes described as the first volar interosseous muscle.

Nerves.—The first and second *Lumbricales* are supplied by the sixth and seventh cervical nerves through the third and fourth digital branches of the median nerve; the third and fourth *Lumbricales* and all the *Interossei* are supplied by the eighth cervical nerve, through the deep palmar branch of the ulnar nerve. The third *Lumbricalis* frequently receives a twig from the median nerve.

Actions.—The *Interossei volares* adduct the fingers to an imaginary line drawn longitudinally through the centre of the middle finger; and the *Interossei dorsales*

abduct the fingers from that line. The Interossei, in conjunction with the Lumbricales, flex the first phalanges, and, in consequence of their insertions into the expansions of the Extensor tendons, extend the second and third phalanges. The Extensor digitorum communis is believed to act almost entirely on the first phalanges.

Applied Anatomy.—In considering the actions of the various muscles upon fractures of the upper extremity, the most common forms of injury have been selected both for illustration and description.

Fracture of the middle of the clavicle (fig. 566) is usually attended with considerable displacement of the lateral fragment, which is drawn downwards and medialwards, and at the same time rotated, so that its lateral end is carried forwards and its medial end backwards.

The displacement is produced as follows: the lateral fragment is drawn downwards by the weight of the arm, the Trapezius not being able to support this. It is drawn medialwards by the Subclavius and Pectoralis minor, possibly assisted by the Pectoralis major

FIG. 566.—Fracture of the middle of the clavicle.

FIG. 567.—Fracture of the surgical neck of the humerus.

and Latissimus dorsi; and is rotated on an axis drawn through its own centre by the Serratus anterior, which causes the scapula to rotate on the wall of the chest, and carries the acromion and the end of the lateral fragment of the clavicle forwards, and so carries the medial end of the lateral portion backwards. The causes of displacement having been ascertained, it is easy to apply the appropriate treatment. The lateral fragment is to be drawn lateralwards, and, together with the scapula, raised to a level with the medial fragment, and retained in that position.

In fracture of the *acromial end of the clavicle*, between the conoid and trapezoid ligaments, only slight displacement occurs, as these ligaments, from their oblique insertion, serve to hold both portions of the bone in apposition. Fracture, also, of the *sternal end*, medial to the costoclavicular ligament, is attended with only slight displacement, this ligament serving to retain the fragments in close apposition.

Fracture of the *acromion* is usually caused by violence applied to the upper and lateral part of the shoulder. There is great displacement; the lateral fragment being drawn downwards by the weight of the arm, and rotated forwards and medialwards, so that it forms a right angle with the rest of the bone.

Fracture of the *surgical neck of the humerus* (fig. 567) is very common. It is attended with considerable displacement, and its appearances correspond somewhat with those of dislocation of the head of the humerus into the axilla. The upper fragment remains in its place under the coraco-acromial ligament; the lower is drawn medialwards by the Pectoralis major, Latissimus dorsi, and Teres major; and the humerus is thrown obliquely from the side of the chest by the Deltoides, and occasionally elevated so as to cause the upper end of the lower fragment to project beneath and in front of the coracoid process. The deformity is reduced by fixing the shoulder, and drawing the arm lateralwards and downwards. To counteract the opposing muscles, and to keep the fragments in position, a cone-shaped pad should be placed in the axilla, and the arm bandaged to the side by a broad roller passed round the chest in such a manner that the elbow is carried

slightly forwards, so as to throw the upper end of the lower fragment backwards and lateralwards towards the head of the bone. The whole is then covered with a carefully moulded guttapercha or poroplastic shoulder-cap.

In fracture of the *body of the humerus* below the insertion of the Pectoralis major, Latissimus dorsi, and Teres major, and above the insertion of the Deltoideus, there is also considerable deformity, the upper fragment being drawn medialwards by the first-mentioned muscles, and the lower fragment upwards and lateralwards by the Deltoideus. Shortening of the limb results, with a considerable prominence at the seat of fracture, from the fractured ends of the bone riding over one another, especially if the fracture take place in an oblique direction. The fragments may be brought into apposition by extension from the elbow, and retained in that position by adopting the same means as in the preceding injury.

In fracture of the *body of the humerus* immediately below the insertion of the Deltoideus the amount of deformity depends greatly upon the direction of the fracture. If it occur in a transverse direction, only slight displacement takes place, the upper fragment being drawn a little forwards; but in oblique fracture, the combined actions of the Biceps brachii and Brachialis in front and the Triceps brachii behind draw upwards the lower fragment, causing it to glide over the upper, either backwards or forwards,

FIG. 568.—Fracture of the humerus above the condyles.

FIG. 569.—Fracture of the olecranon.

according to the direction of the fracture. Simple extension reduces the deformity, and the application of a shoulder-cap and splints to the arm will retain the fragments in apposition.

Fracture of the *humerus* immediately above the condyles (fig. 568) deserves very attentive consideration, as the general appearances correspond somewhat with those produced by separation of the epiphysis of the humerus, and with those of dislocation of the radius and ulna backwards. If the direction of the fracture is oblique, from above, downwards and forwards, the lower fragment is drawn upwards by the Brachialis and Biceps brachii in front, and the Triceps brachii behind; and at the same time is drawn backwards behind the upper fragment by the Triceps brachii. This fracture may be diagnosed from dislocation, by the increased mobility, the existence of crepitus, and the fact that the deformity is remedied by extension, but is reproduced on the discontinuance of it. The age of the patient is of importance in distinguishing this form of injury from separation of the epiphysis. In some cases where the injury has been produced by falls on the elbow, the lower fragment is drawn upwards and forwards, causing a considerable prominence in front, the upper fragment projecting backwards beneath the tendon of the Triceps brachii.

In fracture of the *olecranon* (fig. 569) the detached fragment is displaced upwards from 1 cm. to 5 cm. by the action of the Triceps brachii; the prominence of the elbow is consequently lost, and a deep hollow is felt at the back part of the joint, which is much increased on flexing the limb. The patient at the same time loses, more or less, the power of extending the forearm. The treatment consists in wiring the fragments together; but if for some reason this operation is not desirable, they should be approximated by strapping or a figure-of-8 bandage, and the arm put up in an extended position in order to relax the Triceps brachii. Massage and passive movements must be employed early, for fear of ankylosis. Union, when wiring is not resorted to, is usually fibrous.

In fracture of the *radius* below the insertion of the Biceps brachii, but above the insertion of the Pronator teres, the upper fragment is strongly supinated by the Biceps

brachii and Supinator, and at the same time drawn forwards by the Biceps brachii, the lower fragment is pronated and drawn towards the ulna by both Pronators. Thus there is extreme displacement with very little deformity. In treating such a fracture the arm must be put up in a position of supination, otherwise union will take place with great impairment of the movements of the hand. In fractures of the radius below the insertion of the Pronator teres (fig. 570), the upper fragment is drawn upwards by the Biceps brachii and medialwards by the Pronator teres, into a position midway between pronation and supination, and a degree of fulness in the upper half of the forearm is thus produced. The lower fragment is drawn downwards towards the ulna and pronated by the Pronator quadratus; at the same time, the Brachioradialis, by elevating the styloid process, into which it is inserted, will serve to depress the upper end of the lower fragment still more towards the ulna. In order to relax the opposing muscles the elbow should be flexed, and the limb placed in a position midway between pronation and supination; the fracture is then easily reduced by extension from the wrist and elbow. Well-padded splints should be applied on both sides of the forearm from the elbow to the wrist.

In fracture of the *body of the ulna* the upper fragment retains its usual position, but the lower is drawn towards the radius by the pronator quadratus, producing a well-marked depression at the seat of fracture, and some fulness on the dorsal and volar surfaces of the

FIG. 570.—Fracture of the body of the radius.

forearm. The fracture is easily reduced by extension from the wrist and elbow. The forearm should be flexed, and placed in a position midway between pronation and supination, and well-padded splints applied from the elbow to the ends of the fingers.

In fracture of the *bodies of the radius and ulna together*, the lower fragments are drawn upwards, sometimes forwards, sometimes backwards, according to the direction of the fracture, by the combined actions of the flexor and extensor muscles, producing a degree of fulness on either the dorsal or volar surface of the forearm. At the same time the lower fragments are drawn into contact by the Pronator quadratus, the radius being in a state of pronation. The upper fragment of the radius is drawn upwards and medialwards by the Biceps brachii and Pronator teres to a higher level than the ulna; the upper portion of the ulna is slightly elevated by the Brachialis. The fracture may be reduced by extension from the wrist and elbow, and the forearm should be placed in the same position as in fracture of the ulna.

In fracture of the *lower end of the radius* (fig. 571) the displacement produced is very considerable, and bears some resemblance to dislocation of the carpus backwards, from which it should be carefully distinguished. The lower fragment is displaced backwards

FIG. 571.—Fracture of the lower end of the radius.

and upwards, but this displacement is due to the force of the blow driving the portion of the bone into this position, and not to any muscular influence. The upper fragment projects forwards, often lacerating the substance of the Pronator quadratus, and is drawn by this muscle into close contact with the lower end of the ulna, causing a projection on the volar surface of the forearm, immediately above the carpus, from the Flexor tendons being thrust forwards. This fracture may be distinguished from dislocation by the relative positions of the styloid processes of the radius and ulna (the former of which is displaced upwards in fracture) and by the deformity being removed on making sufficient extension, when crepitus may be occasionally detected. The age of the patient will assist in determining whether the injury is fracture or separation of the epiphysis. The treatment consists in flexing the forearm, and making powerful extension from the wrist and elbow, depressing at the same time the radial side of the hand, and retaining the parts in a position of adduction towards the ulnar side.

FASCIÆ AND MUSCLES OF THE LOWER EXTREMITY

The muscles of the lower extremity are subdivided into groups corresponding with the different regions of the limb.

- I. Muscles of the iliac region.
- II. Muscles of the thigh.

- III. Muscles of the leg.
- IV. Muscles of the foot.

I. MUSCLES OF THE ILIAC REGION (fig. 572)

Psoas major.

Psoas minor.

Iliacus.

The **fascia iliaca** covers the Psoas and Iliacus. It is thin above, and becomes gradually thicker as it approaches the inguinal ligament.

The *portion covering the Psoas* is thickened above to form the medial lumbo-costal arch, which stretches from the transverse process of the first to the body of the second lumbar vertebra. Medially, it is attached by a series of arched processes to the intervertebral fibrocartilages, and prominent margins of the bodies of the vertebræ, and to the upper part of the sacrum; the intervals opposite the constricted portions of the bodies transmit the lumbar arteries and veins and filaments of the sympathetic trunk. Laterally, above the crest of the ilium, it is continuous with the fascia covering the front of the Quadratus lumborum (see p. 466), while below the crest of the ilium it is continuous with the fascia covering the Iliacus.

The *portion covering the Iliacus* is connected, laterally, to the whole length of the inner lip of the iliac crest; and medially, to the linea terminalis or brim of the lesser pelvis, where it blends with the periosteum. It is attached to the iliopectineal eminence where it receives the tendon of insertion of the Psoas minor, when that muscle exists. The external iliac vessels lie in front of it, but the branches of the lumbar plexus are behind it; it is separated from the peritoneum by a layer of subperitoneal areolar tissue (fascia of Abernethy).

Laterally to the femoral vessels, the iliac fascia is intimately connected to the posterior margin of the inguinal ligament, and is continuous with the transversalis fascia. It passes behind the femoral vessels, and beyond the inguinal ligament becomes the *iliopectineal fascia*. This fascia divides the space between the inguinal ligament and the hip-bone into two lacunæ or compartments, the medial of which transmits the femoral vessels, the lateral the Psoas major, the Iliacus and the femoral nerve. Medially to the vessels the iliopectineal fascia is attached to the pecten pubis, where it is continuous with the pectineal fascia. On the thigh the iliopectineal fascia covers the Iliacus and the Psoas major, and forms the posterior wall of the femoral sheath; in this region it is the deep layer of the fascia lata.

The **Psoas major** (fig. 572) is a long fusiform muscle placed on the side of the lumbar region of the vertebral column and the brim of the lesser pelvis. It arises (1) from the anterior surfaces and lower borders of the transverse processes of all the lumbar vertebræ; (2) by five slips or digitations, each of which takes origin from the bodies of two vertebræ and their intervertebral fibrocartilage: the highest slip arises from the lower margin of the body of the twelfth thoracic vertebra, the upper margin of the body of the first lumbar vertebra and the interposed fibrocartilage, the lowest slip from the adjacent margins of the bodies of the fourth and fifth lumbar vertebræ and the interposed fibrocartilage; (3) from a series of tendinous arches which extend across the constricted parts of the bodies of the lumbar vertebræ between the preceding slips; the lumbar arteries and veins, and filaments from the sympathetic trunk, pass beneath these tendinous arches. The muscle proceeds downwards across the brim of the lesser pelvis, and, diminishing gradually in size, passes behind the inguinal ligament and in front of the capsule of the hip-joint, and ends in a tendon: the latter receives nearly the whole of the fibres of the Iliacus and is inserted into the lower and posterior part of the lesser

FIG. 572.—Muscles of the iliac and anterior femoral regions.

trochanter of the femur. A large bursa, which may communicate with the cavity of the hip-joint, separates the tendon from the os pubis and the capsule of the joint.

Relations.—In the abdomen the Psoas major is in relation by its *anterior surface* with the medial lumbocostal arch, the fascia covering the muscle, the extraperitoneal fat and peritoneum, the kidney, Psoas minor, renal vessels, ureter, spermatic vessels, and genitofemoral nerve. In front of the right Psoas is the inferior vena cava and the terminal portion of the ileum, and in front of the left the colon. By its *posterior surface* it is in relation with the transverse processes of the lumbar vertebrae, and the Quadratus lumborum. The lumbar plexus is situated in the posterior part of the substance of the muscle. By its *medial side*, the muscle is in relation with the bodies of the lumbar vertebrae, the lumbar arteries, the gangliated trunk of the sympathetic, and the lumbar lymph glands; with the inferior vena cava on the right, and the aorta on the left side, and along the brim of the pelvis with the external iliac artery.

In the thigh it is in relation, in front, with the fascia lata; behind, with the capsule of the hip-joint, from which it is separated by a bursa; by its *medial border*, with the Pectineus and medial femoral circumflex artery, and also with the femoral artery, which slightly overlaps it; by its *lateral border*, with the Iliacus.

The femoral nerve descends at first through the fibres of Psoas major, then lies between it and the Iliacus, and at the level of the inguinal ligament is in front of the muscle.

The Psoas minor (fig. 572) is placed in front of the Psoas major. It arises from the sides of the bodies of the twelfth thoracic and first lumbar vertebrae and from the fibrocartilage between them. It ends in a long flat tendon which is inserted into the pecten pubis and iliopectineal eminence, and, by its lateral border, into the iliac fascia. This muscle is absent in about 40 per cent. of cases.

The Iliacus (fig. 572) is a flat, triangular muscle, which fills the iliac fossa. It arises from the upper two-thirds of this fossa, and from the inner lip of the iliac crest: behind, from the anterior sacro-iliac and the iliolumbar ligaments, and base of the sacrum; in front, it reaches as far as the anterior superior and anterior inferior iliac spines, and the notch between them. The fibres converge to be inserted into the lateral side of the tendon of the Psoas major, some of them being prolonged on to the body of the femur for about 2.5 cm. below and in front of the lesser trochanter.*

* The Psoas major and Iliacus are sometimes regarded as a single muscle named the *Iliopsoas*.

Relations.—Within the abdomen the Iliacus is in relation by its *anterior surface* with the iliac fascia, which separates the muscle from the extraperitoneal fat and peritonæum, and with the lateral femoral cutaneous nerve; on the right side, with the cæcum; on the left side, with the iliac part of the descending colon; by its *posterior surface*, with the iliac fossa; by its *medial border*, with the Psoas major and femoral nerve.

In the thigh, it is in relation, by its *anterior surface*, with the fascia lata, Rectus femoris, Sartorius, and arteria profunda femoris; by its *posterior surface*, with the capsule of the hip-joint, a bursa common to it and the Psoas major being interposed.

Nerves.—The Psoas major is supplied by branches of the second and third lumbar nerves, the Psoas minor by a branch of the first lumbar nerve, and the Iliacus by branches of the second and third lumbar nerves, through the femoral nerve.

* **Actions.**—The Psoas major, acting from above, flexes the thigh upon the pelvis, being assisted by the Iliacus; acting from below, with the femur fixed, it bends the lumbar portion of the vertebral column forwards and to its own side, and then, in conjunction with the Iliacus, tilts the pelvis forwards. When the muscles of both sides act from below, they serve to maintain the erect posture by supporting the vertebral column and pelvis upon the femora, or in continued action bend the trunk and pelvis forwards, as in raising the trunk from the recumbent posture.

The Psoas minor is a tensor of the iliac fascia.

Applied Anatomy.—There is no definite septum between the portions of fascia covering the Psoas and Iliacus respectively, and the fascia is only connected to the subjacent muscles by a quantity of loose connective tissue. When an abscess forms beneath this fascia, as it is very apt to do, the pus is contained in an osseofibrous cavity which is closed on all sides within the abdomen, and is open only at its lower part, where the fascia is prolonged over the muscles into the thigh.

Abscess within the sheath of the Psoas major (*psaos abscess*) is generally due to tuberculous caries of the bodies of the lower thoracic or the lumbar vertebrae. When the disease is in the thoracic region, the matter tracks down the posterior mediastinal cavity in front of the bodies of the vertebrae, and, passing beneath the medial lumbocostal arch, enters the sheath of the Psoas, down which it travels as far as the pelvic brim; it then gets beneath the iliac portion of the fascia, and fills up the iliac fossa. In consequence of the attachment of the fascia to the linea terminalis, it rarely finds its way into the lesser pelvis, but passes by a narrow opening under the inguinal ligament into the thigh, laterally to the femoral vessels. It thus follows that a psaos abscess may be described as consisting of four parts: (1) a somewhat narrow channel at its upper part, in the psaos sheath; (2) a dilated sac in the iliac fossa; (3) a constricted neck under the inguinal ligament; and (4) a dilated sac in the upper part of the thigh. When the lumbar vertebrae are the seat of the disease, the matter finds its way directly into the substance of the Psoas. The muscular fibres are destroyed, and the nerves contained in the abscess are isolated and exposed in its interior; the iliac vessels which lie in front of the fascia remain intact, and the peritonæum seldom becomes implicated. All psaos abscesses do not, however, pursue this course; the pus may leave the sheath of the muscle above the crest of the ilium, and tracking backwards may point in the loin (*lumbar abscess*); or it may point above the inguinal ligament in the inguinal region; or it may follow the course of the branches of the hypogastric vessels into the lesser pelvis, and, passing through the greater sciatic foramen, discharge itself on the back of the thigh.

II. MUSCLES OF THE THIGH

1. ANTERIOR FEMORAL MUSCLES (fig. 572)

Tensor fasciæ latæ.	Quadriceps	{ Rectus femoris. Vastus lateralis. Vastus medialis. Vastus intermedius.
Sartorius.	femoris	
Articularis genus.		

The superficial fascia forms a continuous layer over the whole of the thigh; it consists of areolar tissue containing in its meshes much fat, and may be separated into two or more layers, between which are found the superficial vessels and nerves. It varies in thickness in different parts of the limb; in the groin it is thick, and the two layers are separated from one another by the superficial inguinal lymph-glands, the great saphenous vein, and several smaller vessels. The superficial layer is continuous above with the superficial fascia of the abdomen. The deep layer of the superficial fascia is a

very thin, fibrous stratum, best marked on the medial side of the great saphenous vein and below the inguinal ligament. It is placed beneath the subcutaneous vessels and nerves and upon the surface of the fascia lata. It is intimately adherent to the fascia lata a little below the inguinal ligament. It covers the fossa ovalis (saphenous opening), being closely united to its circumference, and is connected to the sheath of the femoral vessels. The portion covering the fossa ovalis is perforated by the great saphenous vein and by blood and lymphatic vessels, hence it has been termed the *fascia cribrosa*, the openings for these vessels having been likened to the holes in a sieve. A large subcutaneous bursa is found in the superficial fascia over the patella.

The **deep fascia** of the thigh is named, from its great extent, the *fascia lata*: it constitutes an investment for the whole of this region of the limb, but varies in thickness in different parts. Thus, it is thicker in the upper and lateral part of the thigh, where it receives a fibrous expansion from the Glutæus maximus, and where the Tensor fasciæ latæ is inserted between its layers; it is very thin behind, and at the upper and medial part, where it covers the Adductor muscles, but becomes stronger around the knee, where it receives fibrous expansions from the tendon of the Biceps femoris laterally, from the Sartorius medially, and from the Quadriceps femoris in front. The fascia lata is attached, above and behind, to the back of the sacrum and coccyx; laterally, to the iliac crest; in front, to the inguinal ligament and to the superior ramus of the os pubis; and medially, to the inferior ramus of the os pubis, to the inferior ramus and tuberosity of the ischium, and to the lower border of the sacrotuberous ligament. From its attachment to the iliac crest it descends as a dense fascia over the Glutæus medius to the upper border of the Glutæus maximus, where it splits into two layers, one passing superficial and the other deep to this muscle; at the lower border of the muscle the two layers reunite. Laterally, the fascia lata receives the greater part of the insertion of the Glutæus maximus, and becomes proportionately thicker. The portion of the fascia lata attached to the front part of the iliac crest, and corresponding to the origin of the Tensor fasciæ latæ, extends down the lateral side of the thigh as two layers, one superficial and the other deep to this muscle; at the lower end of the muscle these two layers unite, and form a strong band, having first received the insertion of the muscle. This band is continued downwards, under the name of the *iliotibial tract* (iliotibial band), and is attached to the lateral condyle of the tibia. The part of the Iliotibial tract which lies deep to the Tensor fasciæ latæ is prolonged upwards to join the lateral part of the capsule of the hip-joint. The fascia lata is attached to all the prominent points around the knee-joint, viz. the condyles of the femur and tibia, and the head of the fibula. On either side of the patella it is strengthened by transverse fibres from the lower parts of the Vasti, which are attached to and support this bone. Of these the lateral are stronger, and are continuous with the iliotibial tract. The fascia lata gives off two strong intermuscular septa, which are attached to the whole length of the linea aspera of the femur and its prolongations above and below: the lateral and stronger septum, which extends from the insertion of the Glutæus maximus to the lateral condyle, separates the Vastus lateralis in front from the short head of the Biceps femoris behind, and gives partial origin to these muscles; the medial and thinner septum separates the Vastus medialis from the Adductors and the Pectineus. Besides these there are numerous smaller septa, separating the individual muscles, and enclosing each in a distinct sheath.

The **fossa ovalis** (saphenous opening) (fig. 573).—At the upper and medial part of the thigh, a little below the medial end of the inguinal ligament, is a large oval aperture in the fascia lata; it transmits the great saphenous vein, and other smaller vessels, and is termed the *fossa ovalis*. The *fascia cribrosa*, which is pierced by the structures passing through the opening, closes the aperture and must be removed to expose it. The fascia lata in this part of the thigh is described as consisting of a superficial and a deep portion.

The **superficial portion** of the fascia lata is the part on the lateral side of the fossa ovalis. It is attached to the crest and anterior superior spine of the ilium, to the whole length of the inguinal ligament, and to the pecten pubis in conjunction with the lacunar ligament. From the tubercle of the os pubis it is reflected downwards and lateralwards, as an arched margin, the *falciform*

margin, forming the lateral boundary of the fossa ovalis ; this margin overlies and is adherent to the anterior layer of the sheath of the femoral vessels : to its edge is attached the fascia cribrrosa. The upward and medial prolongation of the falciform margin is named the *superior cornu* ; its downward and medial prolongation, the *inferior cornu*. The latter is well defined, and is continuous behind the great saphenous vein with the pectineal fascia.

The *deep portion* is situated on the medial side of the fossa ovalis, and is continuous with the superficial portion at the lower margin of the fossa : traced upwards, it covers the Pectineus, Adductor longus, and Gracilis, and, passing behind the sheath of the femoral vessels, to which it is closely united, is continuous with the iliopectineal fascia, and is attached to the pecten pubis.

FIG. 573.—The fossa ovalis

From this description it may be observed that the superficial portion of the fascia lata lies in front of the femoral vessels, and the deep portion behind them, so that an apparent aperture exists between the two, through which the great saphenous passes to join the femoral vein.

The **Tensor fasciæ latæ** arises from the anterior 5 cm. of the outer lip of the iliac crest ; from the outer surface of the anterior superior iliac spine, and part of the outer border of the notch below it, between the Glutæus medius and Sartorius ; and from the deep surface of the fascia lata. It is inserted between the two layers of the iliotibial tract of the fascia lata about the junction of the middle with the upper third of the thigh.

The **Sartorius**, the longest muscle in the body, is narrow and ribbon-like ; it arises by tendinous fibres from the anterior superior iliac spine and the upper half of the notch below it. It crosses obliquely the upper and anterior parts of the thigh, from the lateral to the medial side, then descends vertically,

as far as the medial side of the knee, passing behind the medial condyle of the femur to end in a tendon. This curves obliquely forwards and expands into a broad aponeurosis, which is inserted, in front of the Gracilis and Semitendinosus, into the upper part of the medial surface of the body of the tibia, nearly as far forwards as the anterior crest. The upper part of the aponeurosis is curved backwards over the upper edge of the tendon of the Gracilis so as to be inserted behind it. An offset, from its upper margin, blends with the capsule of the knee-joint, and another, from its lower border, with the fascia on the medial side of the leg.

The relations of this muscle to the femoral artery are important, as it constitutes the chief guide in tying the vessel. In the upper third of the thigh it forms the lateral side of a triangle, the *femoral (Scarpa's) triangle*, the medial side of which is formed by the medial border of the Adductor longus, and the base, directed upwards, by the inguinal ligament; the femoral artery passes through the middle of this space from its base to its apex. In the middle third of the thigh, the femoral artery is contained in the *adductor (Hunter's) canal*, on the roof of which the Sartorius lies.

The **Quadriceps femoris** is the great extensor muscle of the leg, and consists of a large fleshy mass which covers the front and sides of the femur. It is subdivided into separate portions, which have received distinctive names. One occupying the middle of the thigh, and connected above with the ilium, is called from its straight course the *Rectus femoris*. The other three lie in immediate connexion with the body of the femur, which they cover from the trochanters to the condyles; that on the lateral side of the femur is termed the *Vastus lateralis*; that on the medial side, the *Vastus medialis*; and that in front, the *Vastus intermedius*.

The **Rectus femoris** is fusiform in shape, and its superficial fibres are arranged in a bipennate manner, the deep fibres running straight down to the deep aponeurosis. It arises by two tendons: an anterior or straight, from the anterior inferior iliac spine, and a posterior or reflected, from a groove above the brim of the acetabulum. The two unite at an acute angle, and spread into an aponeurosis which is prolonged downwards on the anterior surface of the muscle, and from this the muscular fibres arise. The muscle ends in a broad and thick aponeurosis which occupies the lower two-thirds of its posterior surface, and, gradually becoming narrowed into a flattened tendon, is inserted into the base of the patella.

The **Vastus lateralis** is the largest part of the Quadriceps femoris. It arises by a broad aponeurosis, which is attached to the upper part of the intertrochanteric line, to the anterior and inferior borders of the greater trochanter, to the lateral lip of the gluteal tuberosity, and to the upper half of the lateral lip of the linea aspera: this aponeurosis covers the upper three-fourths of the muscle, and from its deep surface many fibres take origin. A few additional fibres arise from the tendon of the Gluteus maximus, and from the lateral intermuscular septum between the Vastus lateralis and short head of the Biceps femoris. The fibres form a large fleshy mass, which is attached to a strong aponeurosis, placed on the deep surface of the lower part of the muscle: this aponeurosis contracts into a flat tendon which is inserted into the lateral border of the patella, blending with the Quadriceps femoris tendon, and giving an expansion to the capsule of the knee-joint.

The Vastus medialis and Vastus intermedius appear to be inseparably united, but when the Rectus femoris has been reflected a narrow interval will be observed extending upwards from the medial border of the patella between the two muscles, and the separation may be carried to the lower part of the intertrochanteric line, where, however, the two muscles are frequently continuous.

The **Vastus medialis** arises from the lower half of the intertrochanteric line, the medial lip of the linea aspera, the upper part of the medial supracondylar line, the tendons of the Adductor longus and Adductor magnus, and the medial intermuscular septum. Its fibres are directed downwards and forwards, and are chiefly attached to an aponeurosis which lies on the deep surface of the muscle and is inserted into the medial border of the patella, and the Quadriceps femoris tendon, an expansion being sent to the capsule of the knee-joint.

The **Vastus intermedius** (*Crureus*) arises from the front and lateral surfaces of the body of the femur in its upper two-thirds and from the lower part of the lateral intermuscular septum. Its fibres end in a superficial aponeurosis, which forms the deep part of the *Quadriceps femoris* tendon.

The *tendons* of the different portions of the *Quadriceps* unite at the lower part of the thigh, to form a single strong tendon, which is inserted into the base of the patella, some fibres passing over it to blend with the *ligamentum patellæ*. More properly, the patella may be regarded as a sesamoid bone developed in the tendon of the *Quadriceps*; and the *ligamentum patellæ*, which is continued from the apex of the patella to the tuberosity of the tibia, as the proper tendon of insertion of the muscle, the medial and lateral *patellar retinacula* (p. 400) being expansions from its borders. A bursa, which usually communicates with the cavity of the knee-joint, is situated between the femur and the portion of the *Quadriceps* tendon above the patella; another is interposed between the tendon and the upper part of the front of the tibia (fig. 505).

The **Articularis genus** (*Subcrureus*) is a small muscle, usually distinct from the *Vastus intermedius*, but occasionally blended with it; it consists of several muscular bundles which arise from the anterior surface of the lower part of the body of the femur, and are inserted into the upper part of the capsule of the knee-joint.

Nerves.—The *Tensor fasciæ latæ* is supplied by the fourth and fifth lumbar and first sacral nerves through the superior gluteal nerve; the other muscles of this region, by the second, third, and fourth lumbar nerves, through the femoral nerve.

Actions.—The *Tensor fasciæ latæ* is a tensor of the *fascia lata*; continuing its action, the oblique direction of its fibres enables it to abduct the thigh and to rotate it inwards. In the erect posture, acting from below, it will serve to steady the pelvis upon the head of the femur; by means of the *iliotibial tract* it steadies the condyles of the femur on the articular surfaces of the tibia, and assists the *Glutæus maximus* in supporting the knee in the extended position. The *Sartorius* flexes the leg upon the thigh, and, continuing to act, flexes the thigh upon the pelvis; it next abducts and rotates the thigh outwards. When the knee is bent, the *Sartorius* assists the *Semitendinosus*, *Semimembranosus*, and *Popliteus* in rotating the tibia inwards. Taking its fixed point from the leg, it flexes the pelvis upon the thigh, and, if one muscle only acts, assists in rotating the pelvis. The *Quadriceps femoris* extends the leg upon the thigh. The *Rectus femoris* assists the *Psoas major* and *Iliacus* in supporting the pelvis and trunk upon the femur. It also assists in flexing the thigh on the pelvis, or if the thigh be fixed it will flex the pelvis. The *Vastus medialis* draws the patella medialwards as well as upwards.

Applied Anatomy.—A few fibres of the *Rectus femoris* are occasionally ruptured from severe strain. This accident is especially liable to occur during the games of football and cricket, and is sometimes known as 'cricket thigh.' The patient experiences a sudden pain in the part, as if he had been struck, and the *Rectus* stands out and is felt to be tense and rigid. The accident is often followed by considerable swelling from inflammatory effusion. Occasionally the *Quadriceps femoris* may be torn away from its insertion into the patella; or the *ligamentum patellæ* may be ruptured about 2·5 cm. above the bone. This accident is caused in the same manner as fracture of the patella by muscular action, viz. by a violent muscular effort to prevent falling while the knee is in a position of semi-flexion. A distinct gap can be felt above the patella, and, owing to the retraction of the muscular fibres, union may fail to take place.

2. MEDIAL FEMORAL MUSCLES

Gracilis.

Adductor longus.

Adductor magnus.

Pectineus.

Adductor brevis.

The **Gracilis** (fig. 572) is the most superficial muscle on the medial side of the thigh. It is thin and flattened, broad above, narrow and tapering below. It arises by a thin aponeurosis from the anterior margins of the lower half of the symphysis pubis and the upper half of the pubic arch. The fibres run vertically downwards, and end in a rounded tendon, which passes behind the medial condyle of the femur, curves round the medial condyle of the tibia, where it becomes flattened, and is inserted into the upper part of the medial surface

of the body of the tibia, below the condyle. A few of the fibres of the lower part of the tendon are prolonged into the deep fascia of the leg. At its

FIG. 574.—Deep muscles of the medial femoral region.

insertion the tendon is situated immediately above that of the Semitendinosus, and its upper edge is overlapped by the tendon of the Sartorius, with which it is in part blended. It is separated from the tibial collateral ligament of the knee-joint by a bursa common to it and the tendon of the Semitendinosus.

The **Pectineus** (fig. 572) is a flat, quadrangular muscle, situated at the anterior part of the upper and medial aspect of the thigh. It arises from the pecten pubis, and to a slight extent from the surface of bone in front of it, between the iliopectineal eminence and pubic tubercle, and from the fascia covering the anterior surface of the muscle; the fibres pass downwards, backwards, and lateralwards, to be inserted into the femur, along a line leading from the lesser trochanter to the linea aspera.

Relations.—Its *anterior surface* is in relation with the fascia lata, which separates it from the femoral vessels and great saphenous vein; its *posterior surface*, with the capsule of the hip-joint, the Adductor brevis, Obturator externus, and the anterior branch of the obturator nerve; its *lateral border*, with the Psoas major and the medial femoral circumflex vessels; its *medial border*, with the margin of the Adductor longus.

The **Adductor longus** (fig. 574), the most superficial of the three adductors, is a triangular muscle, lying in the same plane as the Pectineus. It arises by a flat, narrow tendon, from the front of the os pubis in the angle between the crest and the symphysis. It soon expands into a broad fleshy belly which passes downwards, backwards, and lateralwards, and is inserted, by an aponeurosis, into the middle third of the linea aspera of the femur, between the Vastus medialis and the Adductor magnus, with both of which it is usually blended.

Relations.—Its *anterior surface* is in relation with the fascia lata, the Sartorius, and, near its insertion, with the femoral artery and vein; its *posterior surface*, with the Adductores brevis and magnus, the anterior branch of the obturator nerve, and near its insertion with the profunda femoris vessels; its *lateral border*, with the Pectineus; its *medial border*, with the Gracilis.

The **Adductor brevis** (fig. 574) is situated immediately behind the two preceding muscles. It is somewhat triangular in form, and arises by a narrow origin from the outer surface of the inferior ramus of the os pubis, between

the Gracilis and Obturator externus. Its fibres, passing backwards, lateralwards, and downwards, are inserted, by an aponeurosis, into the femur, along the line leading from the lesser trochanter to the linea aspera and into the upper part of the linea aspera, immediately behind the Pectineus and upper part of the Adductor longus.

Relations.—Its *anterior surface* is in relation with the Pectineus, Adductor longus, arteria profunda femoris, and anterior branch of the obturator nerve; its *posterior surface*, with the Adductor magnus, and posterior branch of the obturator nerve; its *lateral border*, with the medial femoral circumflex artery, the Obturator externus, and conjoint tendon of the Psoas major and Iliacus: its *medial border*, with the Gracilis and Adductor magnus. It is pierced near its insertion by the second, or first and second, perforating branches of the arteria profunda femoris.

The **Adductor magnus** (fig. 574) is a large triangular muscle, situated on the medial side of the thigh. It arises from a small part of the inferior ramus of the os pubis, from the inferior ramus of the ischium, and from the lateral margin of the inferior part of the tuberosity of the ischium. Those fibres which arise from the ramus of the os pubis are short, horizontal in direction, and are inserted into the rough line leading from the greater trochanter to the linea aspera, medially to the Glutæus maximus*; those from the ramus of the ischium are directed downwards and lateralwards with different degrees of obliquity, to be inserted, by means of a broad aponeurosis, into the linea aspera and the upper part of its medial prolongation below. The medial portion of the muscle, composed principally of the fibres arising from the tuberosity of the ischium, forms a thick fleshy mass which descends almost vertically, and ends about the lower third of the thigh in a rounded tendon which is inserted into the adductor tubercle on the medial condyle of the femur, and is connected by a fibrous expansion to the line leading upwards from the tubercle to the linea aspera. At the insertion of the muscle, there is a series of osseo-aponeurotic openings, formed by tendinous arches attached to the bone. The upper four openings are small, and give passage to the perforating branches of the arteria profunda femoris. The lowest is of large size, and transmits the femoral vessels to the popliteal fossa.

Relations.—Its *anterior surface* is in relation with the Pectineus, Adductores brevis and longus, the femoral and profunda vessels, and the posterior branch of the obturator nerve; its *posterior surface*, with the sciatic nerve, the Glutæus maximus, Biceps femoris, Semitendinosus, and Semimembranosus. Its *superior border* lies parallel with the Quadratus femoris, the superficial branch of the medial femoral circumflex artery passing between them; its *medial border* is in relation with the Gracilis, Sartorius, and fascia lata.

Nerves.—The three Adductors and the Gracilis are supplied by the third and fourth lumbar nerves through the obturator nerve: the Adductor magnus receives an additional branch from the sacral plexus through the sciatic nerve. The Pectineus is supplied by the second, third, and fourth lumbar nerves through the femoral nerve, and by the third lumbar through the accessory obturator nerve when this latter exists. Occasionally it receives a branch from the obturator nerve.†

Actions.—The Pectineus and three Adductores adduct the thigh powerfully; they are especially used in horse exercise, the sides of the saddle being grasped between the knees by the contraction of these muscles; they rotate the thigh outwards, and when the limb has been abducted, they draw it medialwards, carrying the thigh across that of the opposite side. The Pectineus and Adductores brevis and longus assist the Psoas major and Iliacus in flexing the thigh upon the pelvis. In progression, all these muscles assist in drawing forwards the lower limb. The Gracilis assists the Sartorius in flexing the leg and rotating it inwards; it is also an adductor of the thigh. If the lower extremities be fixed, these muscles, taking their fixed points below, may act upon the pelvis, serving to maintain the body in

* These uppermost fibres are sometimes described as a separate muscle—the *Adductor minimus*—which is situated somewhat anteriorly to the other parts of the muscle.

† The Pectineus may consist of two incompletely separated strata: the lateral or dorsal stratum, which is constant, is supplied by a branch from the femoral nerve, or in the absence of this branch by the accessory obturator nerve; the medial or ventral stratum, when present, is supplied by the obturator nerve.—A. M. Paterson, *Journal of Anatomy and Physiology*, vol. xxvi. p. 43.

an erect posture; or, if their action be continued, flex the pelvis forwards upon the femur.

Applied Anatomy.—The Adductor longus is liable to be severely strained in those who ride much on horseback, or its tendon may be ruptured by suddenly gripping the saddle. Occasionally, especially in cavalry soldiers, the tendon becomes ossified, constituting the rider's bone.

3. MUSCLES OF GLUTEAL REGION (fig. 575)

Glutæus maximus.	Obturator internus.
Glutæus medius.	Gemellus superior.
Glutæus minimus.	Gemellus inferior.
Piriformis.	Quadratus femoris.
Obturator externus.	

The **Glutæus maximus**, the largest and most superficial muscle in the glutæal region, is a broad and thick fleshy mass of a quadrilateral shape, and forms the prominence of the nates. Its large size is one of the most characteristic features of the muscular system in man, connected as it is with the power he has of maintaining the trunk in the erect posture. The muscle is remarkably coarse in structure, being made up of fasciuli lying parallel with one another, and collected into large bundles separated by fibrous septa. It arises from the posterior glutæal line of the ilium, and the rough portion of bone, including the crest, immediately above and behind it: from the aponeurosis of the Sacrospinalis; from the posterior surface of the lower part of the sacrum and the side of the coccyx; from the sacrotuberous ligament, and from the fascia (glutæal aponeurosis) covering the Glutæus medius. The fibres run obliquely downwards and lateralwards; those forming the upper and larger portion of the muscle, together with the superficial fibres of the lower portion, end in a thick tendinous lamina, which passes across the greater trochanter, and is inserted into the iliotibial tract of the fascia lata; the deeper fibres of the lower portion of the muscle are inserted into the glutæal tuberosity of the femur between the Vastus lateralis and Adductor magnus.

Three *bursæ* are usually found in relation with the deep surface of this muscle. One, of large size, and generally multilocular, separates it from the greater trochanter; a second, often wanting, is situated on the tuberosity of the ischium; a third is found between the tendon of the muscle and that of the Vastus lateralis.

Relations.—Its *superficial surface* is in relation with a thin fascia which separates it from the subcutaneous tissue; its *deep surface*, with the ilium, sacrum, coccyx, and sacrotuberous ligament, part of the Glutæus medius, Piriformis, Gemelli, Obturator internus, Quadratus femoris, the tuberosity of the ischium, greater trochanter, the origins of the Biceps femoris, Semitendinosus, Semimembranosus, and the Adductor magnus. The superficial part of the superior glutæal artery reaches the deep surface of the muscle by passing between the Piriformis and the Glutæus medius; the inferior glutæal and internal pudendal vessels and the sciatic, pudendal, and lateral femoral cutaneous nerves, and muscular branches from the sacral plexus, issue from the pelvis below the Piriformis. The first perforating artery and the terminal branches of the medial circumflex femoral artery are also found under cover of the lower part of the muscle. Its *upper border* is thin, and is connected with the Glutæus medius by the glutæal aponeurosis. Its *lower border* is free and prominent, and is crossed by the fold of the nates.

The **Glutæus medius** is a broad, thick, radiating muscle, situated on the outer surface of the pelvis. Its posterior third is covered by the Glutæus maximus, its anterior two-thirds by the glutæal aponeurosis, which separates it from the superficial fascia and integument. It arises from the outer surface of the ilium between the iliac crest and posterior glutæal line above, and the anterior glutæal line below; it also arises from the strong fascia which covers the upper part of its outer surface. The fibres converge to a flattened tendon, which is inserted into the oblique ridge directed downwards and forwards on the lateral surface of the greater trochanter of the femur. A bursa separates the tendon of the muscle from the surface of the trochanter over which it glides.

The **Glutæus minimus**, the smallest of the three Glutæi, is placed immediately beneath the preceding. It is fan-shaped, arising from the outer surface

of the ilium, between the anterior and inferior gluteal lines, and behind, from the margin of the greater sciatic notch. The fibres converge to the deep surface of a radiated aponeurosis, and this ends in a tendon which is inserted into an impression on the anterior border of the greater trochanter of the femur, and gives an expansion to the capsule of the hip-joint. A bursa is interposed between the tendon and the greater trochanter.

Between the *Glutæus medius* and *Glutæus minimus* are the deep branches of the superior gluteal vessels and the superior gluteal nerve. The deep surface of the *Glutæus minimus* is in relation with the reflected tendon of the *Rectus femoris* and the capsule of the hip-joint.

The *Piriformis* lies almost parallel with the posterior margin of the *Glutæus medius*. It is situated partly within the pelvis against its posterior wall, and partly at the back of the hip-joint. It arises from the front of the sacrum by three fleshy digitations, attached to the portions of bone between the anterior sacral foramina, and to the grooves leading from the foramina: a few fibres also arise from the margin of the greater sciatic foramen, and from the anterior surface of the sacrotuberous ligament. The muscle passes out of the pelvis through the greater sciatic foramen, and is inserted by a rounded tendon into the upper border of the greater trochanter of the femur, behind and above, but often partly blended with, the common tendon of the *Obturator internus* and *Gemelli*.

Relations.—Within the pelvis the anterior surface of the *Piriformis* is in relation with the rectum (especially on the left side), the sacral plexus of nerves, and branches of the hypogastric vessels; its posterior surface with the sacrum. Outside the pelvis, its anterior surface is in contact

Fig. 575.—Muscles of the gluteal and posterior femoral regions.

with the posterior surface of the ischium and capsule of the hip-joint; and its *posterior surface*, with the *Glutæus maximus*. Its *upper border* is in relation with the *Glutæus medius*, and the superior glutæal vessels and nerve; its *lower border*, with the *Gemellus superior* and *Coccygeus*. The inferior glutæal and internal pudendal vessels, and the sciatic, posterior femoral cutaneous, and pudendal nerves, and muscular branches from the sacral plexus, appear on the buttock between the *Piriformis* and *Gemellus superior*. The muscle is frequently pierced by the common peronæal nerve.

The **Obturator membrane** (fig. 576) is a thin fibrous sheet, which almost completely closes the obturator foramen. Its fibres are arranged in interlacing bundles mainly transverse in direction; the uppermost bundle is attached to the obturator tubercles and completes the obturator canal for the passage of the obturator vessels and nerve. The membrane is attached to the sharp margin of the obturator foramen except at its lower lateral angle, where it is fixed to the pelvic surface of the inferior ramus of the ischium, i.e. within the margin. Both Obturator muscles are connected with this membrane.

FIG. 576.—The obturator membrane.

The **Obturator internus** is situated partly within the lesser pelvis, and partly at the back of the hip-joint. It arises from the inner surface of the anterolateral wall of the pelvis, where it surrounds the greater part of the obturator foramen, being attached to the inferior rami of the os pubis and ischium and to the inner surface of the hip-bone below and behind the pelvic brim, reaching from the upper part of the greater sciatic foramen above and behind to the obturator foramen below and in front. It also arises from the medial part of the pelvic surface of the obturator membrane, from the tendinous arch which completes the canal for the passage of the obturator vessels and nerve, and to a slight extent from the obturator fascia, which covers the muscle. The fibres converge rapidly towards the lesser sciatic foramen and end in four or five tendinous bands on the deep surface of the muscle; these bands are reflected at a right angle over the grooved surface of the ischium between its spine and tuberosity. The grooved surface is covered by smooth cartilage, which is separated from the tendon by a bursa, and presents one or more ridges corresponding with the furrows between the tendinous bands. These bands leave the pelvis through the lesser sciatic

foramen and unite into a single flattened tendon, which passes horizontally across the capsule of the hip-joint, and, after receiving the attachments of the Gemelli, is inserted into the fore part of the medial surface of the greater trochanter of the femur, above and in front of the trochanteric fossa. A bursa, narrow and elongated in form, is usually found between the tendon and the capsule of the hip-joint; it occasionally communicates with the bursa between the tendon and the ischium.

Relations.—*Within the pelvis*, the anterolateral surface of the muscle is in relation with the obturator membrane and inner surface of the anterior wall of the pelvis; its pelvic surface, with the obturator fascia, and the origin of the Levator ani, and with the internal pudendal vessels and pudendal nerve, which cross it. The pelvic surface forms the lateral boundary of the ischiorectal fossa. *Outside the pelvis*, the muscle is covered by the Glutæus maximus, crossed by the sciatic nerve, and rests on the back of the hip-joint. As the tendon of the Obturator internus emerges from the lesser sciatic foramen it is overlapped both in front and behind by the two Gemelli which form a muscular canal for it; near its insertion the Gemelli pass in front of the tendon and form a groove in which it lies.

The **Gemelli** are two small muscular fasciculi, accessories to the tendon of the Obturator internus which is received into a groove between them.

The **Gemellus superior**, the smaller of the two, arises from the outer surface of the spine of the ischium, blends with the upper part of the tendon of the Obturator internus, and is inserted with it into the medial surface of the greater trochanter of the femur. It is sometimes wanting.

The **Gemellus inferior** arises from the upper part of the tuberosity of the ischium, immediately below the groove for the Obturator internus tendon. It blends with the lower part of the tendon of the Obturator internus, and is inserted with it into the medial surface of the greater trochanter.

The **Quadratus femoris** is a flat, quadrilateral muscle, between the Gemellus inferior and the upper margin of the Adductor magnus; it is separated from the latter by the superficial branch of the medial femoral circumflex artery. It arises from the upper part of the external border of the tuberosity of the ischium, and is inserted into the upper part of the linea quadrata of the femur. A bursa is often found between the front of this muscle and the lesser trochanter.

The **Obturator externus** (fig. 577) is a flat, triangular muscle, which covers the outer surface of the anterior wall of the pelvis. It arises from the margin of bone immediately around the medial side of the obturator foramen, viz. from the rami of the os pubis, and the inferior ramus of the ischium; it also arises from the medial two-thirds of the outer surface of the obturator membrane, and from the tendinous arch which completes the canal for the passage of the obturator vessels and nerves. The fibres springing from the inferior ramus of the ischium extend on to the inner surface of the bone, where they obtain a narrow origin between the margin of the foramen and the attachment of the obturator membrane. The fibres converge and pass backwards, laterally, and upwards, and end in a tendon which runs across the back of the neck of the femur and lower part of the capsule of the hip-joint and is inserted into the trochanteric fossa of the femur. The obturator vessels lie between the muscle and the obturator membrane; the anterior branch of the obturator nerve reaches the thigh by passing in front of the muscle, and the posterior branch by piercing it.

Nerves.—The Glutæus maximus is supplied by the fifth lumbar and first and second sacral nerves through the inferior gluteal nerve; the Glutæi medius and minimus by the fourth and fifth lumbar and first sacral nerves through the superior gluteal nerve; the Piriformis is supplied by the first and second sacral nerves; the Gemellus inferior and Quadratus femoris by the last lumbar and first sacral nerves; the Gemellus superior and Obturator internus by the first, second, and third sacral nerves, and the Obturator externus by the third and fourth lumbar nerves through the obturator nerve.

Actions.—When the Glutæus maximus takes its fixed point from the pelvis, it extends the femur and brings it into line with the trunk. Taking its fixed point below, it supports the pelvis and the trunk upon the head of the femur; this is especially obvious in standing on one leg. Its most powerful action is to raise the

trunk after stooping, by drawing the pelvis backwards, being assisted in this action by the Semitendinosus, Semimembranosus and long head of the Biceps femoris. The Glutæus maximus is a tensor of the fascia lata, and by its connexion with the iliotibial tract steadies the femur on the articular surfaces of the tibia during standing, when the Extensor muscles are relaxed. The lower part of the muscle also acts as an adductor and external rotator of the limb. The Glutæi medius and minimus

FIG. 577.—The Obturator externus.

abduct the thigh when the limb is extended, and are principally called into action in supporting the body on one limb, in conjunction with the Tensor fasciæ latæ. Their anterior fibres draw the greater trochanter forwards and rotate the thigh inwards, in which action they are also assisted by the Tensor fasciæ latæ. The remaining muscles are powerful external rotators of the thigh. When the thigh is flexed upon the pelvis, they cease to act as rotators, and become abductors, with the exception of the Obturator externus, which still rotates the femur outwards.

4. POSTERIOR FEMORAL MUSCLES (fig. 575)

Biceps femoris.

Semitendinosus.

Semimembranosus.

The **Biceps femoris** is situated on the posterolateral aspect of the thigh. It has two heads of origin : one, the long head, arises from the lower and medial impression on the back part of the tuberosity of the ischium, by a tendon common to it and the Semitendinosus, and from the lower part of the sacrotuberous ligament ; the other, the short head, from the lateral lip of the linea aspera of the femur, between the Adductor magnus and Vastus lateralis, extending up almost as high as the insertion of the Glutæus maximus ; from the lateral prolongation of the linea aspera to within 5 cm. of the lateral condyle ; and from the lateral intermuscular septum. The fibres of the long head form a fusiform belly, which passes obliquely downwards and lateralwards across the sciatic nerve to end in an aponeurosis ; this aponeurosis covers the posterior surface of the muscle, receives on its deep surface the fibres of the short head, and gradually contracts into a tendon, which is inserted into the lateral side of the head of the fibula, and by a small slip into the lateral condyle of the tibia. This tendon forms the lateral hamstring and divides into two portions which embrace the fibular collateral ligament of the knee-joint ; from its

posterior border a thin expansion is given off to the fascia of the leg. The common peronæal nerve descends along its medial border.

The **Semitendinosus**, remarkable for the great length of its tendon of insertion, is situated at the posterior and medial aspect of the thigh. It arises from the lower and medial impression on the tuberosity of the ischium, by a tendon common to it and the long head of the Biceps femoris; it also arises from an aponeurosis connecting the adjacent surfaces of the two muscles to the extent of about 7.5 cm. from their origin. The muscle is fusiform and ends a little below the middle of the thigh in a long round tendon which lies along the medial side of the popliteal fossa; the tendon curves around the medial condyle of the tibia, passes over the tibial collateral ligament of the knee-joint, from which it is separated by a bursa, and is inserted into the upper part of the medial surface of the body of the tibia behind the insertion of the Sartorius and below that of the Gracilis. At its insertion it is united with the tendon of the Gracilis and gives off a prolongation to the deep fascia of the leg. A tendinous intersection is usually observed about the middle of the muscle.

The **Semimembranosus**, so called from its membranous tendon of origin, is situated at the back and medial side of the thigh. It arises by a thick tendon from the upper and lateral impression on the tuberosity of the ischium, above and laterally to the Biceps femoris and Semitendinosus, and is inserted into the groove on the back of the medial condyle of the tibia. The tendon of origin expands into an aponeurosis, which passes downwards under cover of the Semitendinosus and long head of the Biceps femoris; from this aponeurosis muscular fibres arise, and converge to another aponeurosis which covers the lower part of the posterior surface of the muscle and contracts into the tendon of insertion. The tendon of insertion gives off certain fibrous expansions: one, of considerable size, passes upwards and lateralwards to be inserted into the back part of the lateral condyle of the femur, forming part of the oblique popliteal ligament of the knee-joint; a second is continued downwards to the fascia which covers the Popliteus muscle; while a few fibres join the tibial collateral ligament of the knee-joint and the fascia of the leg. The muscle overlaps the upper part of the popliteal vessels.

The tendons of insertion of the Semitendinosus and Semimembranosus form the medial hamstrings.

Nerves.—The three muscles are supplied by the fourth and fifth lumbar and the first, second, and third sacral nerves; the short head of the Biceps femoris receives its nerve from the common peronæal nerve; the Semitendinosus, Semimembranosus, and long head of the Biceps femoris are supplied through the tibial nerve.

Actions.—The hamstring muscles flex the leg upon the thigh. When the knee is semiflexed, the Biceps femoris in consequence of its oblique direction rotates the leg slightly outwards; and the Semitendinosus, and to a slight extent the Semimembranosus, rotate the leg inwards, assisting the Popliteus. Taking their fixed point from below, these muscles serve to support the pelvis upon the head of the femur, and to draw the trunk directly backwards, as in raising it from the stooping position or in feats of strength, when the body is thrown backwards in the form of an arch. As already indicated on p. 346, complete flexion of the hip cannot be effected unless the knee-joint is also flexed, on account of the shortness of the hamstring muscles.

Applied Anatomy.—In disease of the knee-joint, contraction of the hamstring tendons is a frequent complication; this causes flexion of the leg, and a partial dislocation of the tibia backwards, with a slight degree of rotation outwards, probably due to the action of the Biceps femoris. The hamstring tendons occasionally require subcutaneous division in some forms of spurious ankylosis of the knee-joint dependent upon permanent contraction and rigidity of the muscles, or from contracture of the ligamentous and other tissues surrounding the joint, the result of disease. The relation of the common peronæal nerve, which lies in close apposition to the medial border of the tendon of the Biceps femoris, must always be borne in mind in dividing this tendon, and a free incision with exposure of the tendon, before division, is the safer proceeding.

III. MUSCLES OF THE LEG

The muscles of the leg may be divided into three groups : anterior, posterior and lateral.

1. ANTERIOR CRURAL MUSCLES (fig. 578)

Tibialis anterior.

Extensor hallucis longus.

Extensor digitorum longus.

Peronæus tertius.

The **fascia cruris** or **deep fascia** of the leg is continuous above with the fascia lata, and is attached around the knee to the patella, the ligamentum patellæ, the tuberosity and condyles of the tibia, and the head of the fibula. Behind, it forms the popliteal fascia which covers the popliteal fossa ; here it is strengthened by transverse fibres, and perforated by the small saphenous vein. It receives an expansion from the tendon of the Biceps femoris laterally, and expansions from the tendons of the Sartorius, Gracilis, Semitendinosus, and Semimembranosus medially ; it blends with the periosteum covering the subcutaneous surface of the tibia, and with that covering the head and malleolus of the fibula ; below, it is continuous with the transverse crural and lacinate ligaments. It is thick and dense in the upper and anterior part of the leg, and gives origin, by its deep surface, to some fibres of the Tibialis anterior and Extensor digitorum longus ; it is thinner behind, where it covers the Gastrocnemius and Soleus. On the lateral side of the leg it gives off the *anterior and posterior fibular intermuscular septa* which are attached respectively to the anterolateral and posterolateral borders of the fibula ; in the anterior and posterior crural regions the fascia also gives off several slender processes which enclose the individual muscles. A broad transverse intermuscular septum, called the *deep transverse fascia of the leg*, intervenes between the superficial and deep posterior crural muscles.

The **Tibialis anterior** is situated on the lateral side of the tibia ; it is thick and fleshy above, tendinous below. It arises from the lateral condyle and upper half or two-thirds of the lateral surface of the body of the tibia ; from the adjoining part of the anterior surface of the interosseous membrane ; from the deep surface of the fascia cruris ; and from the intermuscular septum between it and the Extensor digitorum longus. The fibres run vertically downwards, and end in a tendon which is apparent on the anterior surface of the muscle at the lower third of the leg ; after passing through the medial compartments of the transverse and cruciate crural ligaments, it is inserted into the medial and under surfaces of the first cuneiform bone, and the base of the first metatarsal bone. This muscle overlaps the anterior tibial vessels and deep peronæal nerve in the upper part of the leg.

The **Extensor hallucis longus** is a thin muscle, situated between the Tibialis anterior and the Extensor digitorum longus. It arises from the anterior surface of the fibula for about the middle two-fourths of its extent, medially to the origin of the Extensor digitorum longus ; it also arises from the anterior surface of the interosseous membrane to a similar extent. The anterior tibial vessels and deep peronæal nerve lie between it and the Tibialis anterior. The fibres pass downwards, and end in a tendon, which occupies the anterior border of the muscle, passes through a compartment in the cruciate crural ligament, crosses to the medial side of the anterior tibial vessels near the ankle-joint, and is inserted into the base of the distal phalanx of the great toe. Opposite the metatarsophalangeal articulation a thin prolongation is given off from either side of the tendon and covers the dorsal surface of the joint. An expansion from the medial side of the tendon is usually inserted into the base of the proximal phalanx.

The **Extensor digitorum longus** is a pennate muscle, situated at the lateral part of the front of the leg. It arises from the lateral condyle of the tibia, the upper three-fourths of the anterior surface of the body of the fibula, the upper part of the anterior surface of the interosseous membrane, the deep surface of the fascia cruris, the anterior fibular intermuscular septum and the septum between it and the Tibialis anterior. Between it and the Tibialis

anterior are the upper portions of the anterior tibial vessels and deep peronæal nerve. The tendon passes under the transverse and cruciate crural ligaments in company with the Peronæus tertius, and divides into four slips, which run forward on the dorsum of the foot, and are inserted into the second and third phalanges of the four lesser toes. The tendons to the second, third, and fourth toes are each joined, opposite the metatarsophalangeal articulation, on the lateral side by a tendon of the Extensor digitorum brevis. The tendons are inserted as follows: each receives a fibrous expansion from the corresponding Lumbricalis and Interossei, and then spreads out into a broad aponeurosis, which covers the dorsal surface of the first phalanx: at the articulation of the first with the second phalanx this aponeurosis divides into three slips—an intermediate, which is inserted into the base of the second phalanx; and two collateral slips, which, after uniting with one another on the dorsal surface of the second phalanx, are inserted into the base of the third phalanx.

The *Peronæus tertius* is a part of the *Extensor digitorum longus*, and might be described as its fifth tendon. The fibres belonging to this tendon arise from the lower third or more of the anterior surface of the fibula, the lower part of the anterior surface of the interosseous membrane, and the anterior fibular intermuscular septum. The tendon passes under the transverse and cruciate crural ligaments in the same compartment as the *Extensor digitorum longus*, and is inserted into the dorsal surface of the base of the fifth metatarsal bone, but often spreads into a thin sheet which extends forwards along the shaft of the bone. This muscle is sometimes wanting.

Nerves.—These muscles are supplied by the fourth and fifth lumbar and first sacral nerves through the deep peronæal nerve.

Actions.—The *Tibialis anterior* and *Peronæus tertius* are the direct flexors of the foot at the ankle-joint; the former muscle, when acting in conjunction with the *Tibialis posterior*, raises the medial border of the foot (i.e. inverts the foot); and the latter, acting with the *Peronæi brevis* and *longus*, raises the lateral border of the foot (i.e. everts the foot). The *Extensor digitorum longus* and *Extensor hallucis longus* extend the phalanges of the toes, and, continuing their action, flex the foot upon the leg. Taking their fixed points from below, in the erect posture, all these muscles serve to fix the bones of the leg in the perpendicular position and give increased strength to the ankle-joint.

FIG. 578.—Muscles of the front of the leg.

2. POSTERIOR CRURAL MUSCLES

The muscles of the back of the leg are subdivided into two groups—superficial and deep. Those of the superficial group constitute a

powerful muscular mass, forming the calf of the leg. Their large size is one of the most characteristic features of the muscular apparatus in man, and bears a direct relation to his erect attitude and his mode of progression.

Fig. 579.—Muscles of the back of the leg.—Superficial group.

Superficial Group (fig. 579)

Gastrocnemius. Soleus. Plantaris.

The **Gastrocnemius** is the most superficial muscle, and forms the greater part of the calf. It arises by two heads, which are connected to the condyles of the femur by strong, flat tendons. The medial and larger head takes its origin from a depression at the upper and posterior part of the medial condyle behind the adductor tubercle, and from a rounded tubercle on the popliteal surface of the femur just above the medial condyle. The lateral head arises from an impression on the lateral surface of the lateral condyle and from the lower part of the corresponding epicondylar ridge. Both heads also arise from the subjacent part of the articular capsule of the knee-joint. Each head spreads out into a tendinous expansion which covers the posterior surface of the corresponding part of the muscle. From the anterior surfaces of these tendinous expansions, muscular fibres are given off; those of the medial head being thicker and extending lower than those of the lateral. The fibres unite at an angle in the middle line of the muscle in a tendinous raphe, which expands into a broad aponeurosis on the anterior surface of the muscle, and into this the remaining fibres are inserted. The aponeurosis, gradually contracting, unites with the tendon of the Soleus, and forms with it the tendo calcaneus.

Relations.—The fascia cruris separates the superficial surface of the muscle from the small saphenous vein, and the peroneal anastomotic, medial sural cutaneous, and sural nerves; the common peroneal nerve crosses the lateral head of the muscle, lying partly under cover of Biceps femoris. The deep surface is in relation with the oblique popliteal ligament of the knee-joint, the Popliteus, Soleus, Plantaris, popliteal vessels, and tibial nerve. In front of the tendon of the medial head is a bursa, which, in some cases, communicates with the cavity of the knee-joint. The tendon of the lateral head sometimes contains a sesamoid fibrocartilage or bone, where it plays over the corresponding condyle; and one is occasionally found in the tendon of the medial head.

The **Soleus** is a broad flat muscle situated immediately in front of the Gastrocnemius. It arises by tendinous fibres from the back of the head, and from the upper fourth of the posterior surface of the body of the fibula; from the popliteal line and the middle third of the medial border of the tibia; and from a fibrous band which stretches between these origins and arches over the popliteal vessels and tibial nerve. The tendinous origins from the tibia and

fibula expand and join one another to form a well-marked, coronally placed, intramuscular septum, the anterior and posterior surfaces of which constitute the immediate attachment of the majority of the muscular fibres. The muscular fibres end in an aponeurosis, which covers the posterior surface of the muscle, and, gradually becoming thicker and narrower, joins with the tendon of the Gastrocnemius, and forms with it the tendo calcaneus.

Relations.—Its *superficial surface* is in relation with the Gastrocnemius and Plantaris; its *deep surface*, with the Flexor digitorum longus, Flexor hallucis longus, Tibialis posterior, and posterior tibial vessels and nerve, from all of which it is separated by the deep transverse fascia of the leg.

The Gastrocnemius and Soleus together form a muscular mass which is occasionally described as the *Triceps suræ*; its tendon of insertion is the tendo calcaneus.

The **tendo calcaneus** (tendo Achillis), the common tendon of the Gastrocnemius and Soleus, is the thickest and strongest in the body. It is about 15 cm. long, and begins near the middle of the leg, but receives fleshy fibres on its anterior surface, almost to its lower end. It gradually narrows and thickens until it reaches a level about 4 cm. above the calcaneus; below this level it expands and is inserted into the middle part of the posterior surface of the calcaneus, a bursa being interposed between the tendon and the upper part of this surface.

The **Plantaris** arises from the lower part of the lateral prolongation of the linea aspera, and from the oblique popliteal ligament of the knee-joint. It forms a small fusiform belly, from 7 cm. to 10 cm. long; this ends in a long slender tendon which crosses obliquely between the Gastrocnemius and Soleus, and runs along the medial border of the tendo calcaneus, to be inserted with it into the posterior part of the calcaneus. This muscle is sometimes double, and at other times wanting. Occasionally, its tendon is lost in the lacinate ligament, or in the fascia of the leg.

Nerves.—The Gastrocnemius and Soleus are supplied by the first and second sacral nerves, and the Plantaris by the fourth and fifth lumbar and first sacral nerves, through the tibial nerve.

Actions.—The muscles of the calf are the chief extensors of the foot at the ankle-joint. They possess considerable power, and are called into use in standing, walking, dancing, and leaping; hence the large size they usually present. In walking, these muscles raise the heel from the ground; the body being thus supported on the raised foot, the opposite limb can be carried forwards. In standing, the Soleus, taking its fixed point from below, steadies the leg upon the foot. The Gastrocnemius, acting from below, serves to flex the femur upon the tibia. The Plantaris is the rudiment of a large muscle, the tendon of which in some of the lower animals is continued over the calcaneus to be inserted into the plantar aponeurosis: in man it is an accessory to the Gastrocnemius, extending the ankle if the foot be free, or bending the knee if the foot be fixed.

Deep Group (fig. 580)

Popliteus.

Flexor hallucis longus.

Flexor digitorum longus.

Tibialis posterior.

The **deep transverse fascia** of the leg is a septum between the superficial and deep muscles of the back of the leg. At the sides it is connected to the medial margin of the tibia and the posterolateral border of the fibula. Above, where it covers the Popliteus, it is thick and dense, and receives an expansion from the tendon of the Semimembranosus; it is thinner in the middle of the leg; but below, where it covers the tendons passing behind the malleoli, it is thickened and continuous with the lacinate ligament.

The **Popliteus** is a thin, flat, triangular muscle, which forms the lower part of the floor of the popliteal fossa. It arises by a strong tendon about 2.5 cm. long, from a depression at the anterior part of the groove on the lateral condyle of the femur, and to a small extent from the oblique popliteal ligament of the knee-joint. It is inserted into the medial two-thirds of the triangular surface

above the popliteal line on the posterior surface of the body of the tibia, and into the tendinous expansion covering the muscle.

FIG. 580.—Muscles of the back of the leg. Deep group.

Relations.—Its tendon of origin is covered by the tendon of the Biceps femoris and by the fibular collateral ligament of the knee-joint: it grooves the posterior border of the lateral meniscus, and is invested by the synovial stratum of the capsule of the knee-joint. The fascia covering the muscle separates it from the Gastrocnemius, Plantaris, popliteal vessels, and tibial nerve. The deep surface of the muscle is in contact with the oblique popliteal ligament of the knee-joint and the back of the tibia.

The **Flexor hallucis longus** is situated on the fibular side of the leg. It arises from the inferior two-thirds of the posterior surface of the body of the fibula, with the exception of about 2.5 cm. at its lowest part; from the lower part of the interosseous membrane; from the posterior fibular intermuscular septum, and from the fascia covering the Tibialis posterior. The fibres pass obliquely downwards and backwards, and end in a tendon which occupies nearly the whole length of the posterior surface of the muscle. This tendon lies in a groove which crosses the posterior surface of the lower end of the tibia, the posterior surface of the talus, and the under surface of the sustentaculum tali of the calcaneus. In the sole of the foot it runs forwards between the two heads of the Flexor hallucis brevis, and is inserted into the base of the distal phalanx of the great toe. The grooves on the talus and calcaneus, which contain the tendon of the muscle, are converted by tendinous fibres into a canal which is lined by a mucous sheath. As the tendon passes forwards in the sole of the foot, it is situated above, and crosses from the lateral to the medial side of, the tendon of the Flexor digitorum longus, to which it is connected by a fibrous slip.

Relations.—Its *superficial surface* is in relation with the Soleus and tendo calcaneus, from which it is separated by the deep transverse fascia; its *deep surface*, with the fibula, Tibialis posterior, the peroneal vessels, the lower part of the interosseous membrane, and the ankle-joint; its *lateral border*, with the Peronei; its *medial border*, with the Tibialis posterior, posterior tibial vessels and tibial nerve.

The **Flexor digitorum longus** is situated on the tibial side of the leg. At its origin it is thin and pointed, but it gradually increases in size as it descends. It arises from the posterior surface of the body of the tibia, medially to the tibial origin of the Tibialis posterior; this origin extends from immediately below the popliteal line to within 7 cm. or 8 cm. of the lower extremity of the bone; it also arises from the fascia covering the Tibialis posterior.

The fibres end in a tendon, which runs nearly the whole length of the posterior surface of the muscle. This tendon passes behind the medial malleolus, in a groove common to it and the Tibialis posterior, but separated from the latter by a fibrous septum; each tendon being contained in a special compartment lined

by a separate mucous sheath. It passes obliquely forwards and lateralwards, superficially to the deltoid ligament of the ankle-joint, and deep to the lacinate ligament, and enters the sole of the foot (fig. 584), where it crosses below the tendon of the Flexor hallucis longus, and receives from it a strong tendinous slip. It then expands and is joined by the Quadratus plantæ, and finally divides into four tendons, which are inserted into the bases of the last phalanges of the second, third, fourth, and fifth toes, each tendon passing through an opening in the corresponding tendon of the Flexor digitorum brevis opposite the base of the first phalanx.

Relations.—In the leg its *superficial surface* is in relation with the posterior tibial vessels and tibial nerve, and the deep transverse fascia which separates it from the Soleus; its *deep surface*, with the tibia and Tibialis posterior. In the foot, it is covered by the Abductor hallucis and Flexor digitorum brevis, and crosses superficially to the Flexor hallucis longus.

The Tibialis posterior lies between the Flexor hallucis longus and Flexor digitorum longus, and is the deepest muscle on the back of the leg. It begins above by two pointed processes, separated by an angular interval through which the anterior tibial vessels pass to the front of the leg. It arises from the whole of the posterior surface of the interosseous membrane, with the exception of its lowest part; from the lateral portion of the posterior surface of the body of the tibia, between the commencement of the popliteal line above and the junction of the middle with the lower third of the body below; and from the upper two-thirds of the medial surface of the fibula; some fibres also arise from the deep transverse fascia, and from the intermuscular septa separating it from the adjacent muscles. In the lower fourth of the leg its tendon passes in front of that of the Flexor digitorum longus and lies with it in a groove behind the medial malleolus, but enclosed in a separate sheath; it next passes under the lacinate and over the deltoid ligament into the foot, and then below the plantar calcaneonavicular ligament, where it contains a sesamoid fibrocartilage. It is inserted into the tuberosity of the navicular bone, and gives off fibrous slips, one of which passes backwards and is attached to the sustentaculum tali of the calcaneus, while others pass forwards and lateralwards and are fixed to the three cuneiform bones, the cuboid bone, and the bases of the second, third, and fourth metatarsal bones.

Relations.—Its *superficial surface* is in relation with the Soleus, from which it is separated by the deep transverse fascia, the Flexor digitorum longus, the posterior tibial vessels and tibial nerve, and the peroneal vessels; its *deep surface* with the interosseous membrane, the tibia, fibula, and ankle-joint.

Nerves.—The Popliteus is supplied by the fourth and fifth lumbar and first sacral nerves, the Flexor digitorum longus and Tibialis posterior by the fifth lumbar and first sacral, and the Flexor hallucis longus by the fifth lumbar and the first and second sacral nerves, all through the tibial nerve.

Actions.—The Popliteus assists in flexing the leg upon the thigh; when the leg is flexed, it will rotate the tibia inwards. It is especially called into action at the beginning of the act of bending the knee, inasmuch as it produces the slight inward rotation of the tibia which is essential in the early stage of this movement. The Tibialis posterior is a direct extensor of the foot at the ankle-joint; acting in conjunction with the Tibialis anterior, it turns the sole of the foot upwards and medialwards (i.e. inverts the foot), antagonising the Peronæi, which turn it upwards and lateralwards (evert it). In the sole of the foot the tendon of the Tibialis posterior lies directly below the plantar calcaneonavicular ligament, and is therefore an important factor in maintaining the arch of the foot. The Flexor digitorum longus and Flexor hallucis longus are the direct flexors of the phalanges, and, continuing their action, extend the foot upon the leg; they assist the Gastrocnemius and Soleus in extending the foot, as in the act of walking, or in standing on tiptoe. In consequence of the oblique direction of its tendons the Flexor digitorum longus would draw the toes medialwards, were it not for the Quadratus plantæ, which, inserted into the lateral side of the tendon, draws it to the middle line of the foot. Taking their fixed point from the foot, these muscles serve to maintain the upright posture by steadying the tibia and fibula perpendicularly upon the talus.

3. LATERAL CRURAL MUSCLES (fig. 580)

*Peronæus longus.**Peronæus brevis.*

The *Peronæus longus* is situated at the upper part of the lateral side of the leg, and is the more superficial of the two muscles. It arises from the head, and upper two-thirds of the lateral surface of the body, of the fibula, from the deep surface of the fascia, and from the anterior and posterior fibular intermuscular septa : occasionally also by a few fibres from the lateral condyle of the tibia. Between its attachments to the head and body of the fibula there is a gap through which the common peronæal nerve passes to the front of the leg. It ends in a long tendon, which runs behind the lateral malleolus, in a groove common to it and the tendon of the *Peronæus brevis*, behind which it lies ; the groove is converted into a canal by the superior peronæal retinaculum, and the tendons in it are contained in a common mucous sheath. The tendon then extends obliquely forwards across the lateral side of the calcaneus, below the trochlear process and the tendon of the *Peronæus brevis*, and under cover of the inferior peronæal retinaculum ; it crosses the lateral side of the cuboid bone, and then runs on the under surface of that bone in a groove which is converted into a canal by the long plantar ligament. It then crosses the sole of the foot obliquely, and is inserted into the lateral side of the base of the first metatarsal bone and the lateral side of the first cuneiform bone ; occasionally it sends a slip to the base of the second metatarsal bone. The tendon changes its direction at two points : first, below the lateral malleolus ; secondly, on the cuboid bone ; in both of these situations it is thickened, and, in the latter, a sesamoid fibrocartilage (sometimes a bone) is usually developed in its substance.

The *Peronæus brevis* arises from the lower two-thirds of the lateral surface of the body of the fibula, in front of the *Peronæus longus* ; and from the anterior and posterior fibular intermuscular septa. The fibres pass vertically downwards, and end in a tendon which runs behind the lateral malleolus along with but in front of that of the *Peronæus longus*, the two tendons being enclosed in the same compartment, and lubricated by a common mucous sheath. It then runs forwards on the lateral side of the calcaneus, above the trochlear process and the tendon of the *Peronæus longus*, and is inserted into the tuberosity at the base of the fifth metatarsal bone, on its lateral side.

On the lateral surface of the calcaneus the tendons of the *Peronæi longus* and *brevis* occupy separate osseo-aponeurotic canals formed by the calcaneus and the inferior peronæal reticulum ; each tendon is enveloped by a forward prolongation of the common mucous sheath.

Nerves.—The *Peronæi longus* and *brevis* are supplied by the fourth and fifth lumbar and first sacral nerves through the superficial peronæal nerve.

Actions.—The *Peronæi longus* and *brevis* extend the foot upon the leg, in conjunction with the *Tibialis posterior*, antagonising the *Tibialis anterior* and *Peronæus tertius*. The *Peronæus longus* also everts the foot, and from the oblique direction of its tendon across the sole is an important agent in the maintenance of the transverse arch of the foot. Taking their fixed points below, the *Peronæi* serve to steady the leg upon the foot. This is especially the case in standing upon one leg, when the tendency of the superincumbent weight is to throw the leg medialwards : the *Peronæus longus* overcomes this tendency by drawing on the lateral side of the leg.

Applied Anatomy.—The student should now consider the positions of the tendons of the various muscles of the leg, their relations with the ankle-joint and surrounding blood vessels, and especially their actions upon the foot, as their rigidity and contraction give rise to one or other of the kinds of deformity known as *club foot*. The most simple and common deformity, and one that is rarely, if ever, congenital, is *talipes equinus*, the heel being raised by the rigidity and contraction of the *Gastrocnemius* so that the patient walks upon the ball of the foot. In *talipes varus*, the foot is forcibly adducted and the medial side of the sole raised, sometimes to a right angle with the ground, by the action of the *Tibiales anterior* and *posterior*. In *talipes valgus*, the lateral edge of the foot is raised by the *Peronæi*, and the patient walks on the medial side of the foot. In *talipes calcaneus* the toes are raised by the *Extensor* muscles, the heel is depressed and the patient walks upon it. Other varieties of deformity are met with, as *talipes equinovarus*, *equinovalgus*,

and *calcaneovalgus*, names which sufficiently indicate their nature. Of these, talipes equinovarus is the most common congenital form; the heel is raised by the tendo calcaneus, the medial border of the foot drawn upwards by the Tibialis anterior, the anterior two-thirds twisted medialwards by the Tibialis posterior, and the arch increased by the contraction of the plantar aponeurosis, so that the patient walks on the middle of the lateral border of the foot. Each of these deformities may sometimes be successfully relieved by division of the opposing tendons and fascia; by this means the foot regains its proper position, and the tendons heal by the organisation of lymph thrown out between the divided ends. The operation is easily performed by putting the contracted tendon upon the stretch, and dividing it by means of a narrow, sharp-pointed knife inserted beneath it.

Rupture of a few of the fibres of the Gastrocnemius, or rupture of the Plantaris tendon, not uncommonly occurs, especially in men somewhat advanced in life, from some sudden exertion, and frequently occurs during the game of lawn-tennis, and is hence known as 'lawn-tennis leg.' The accident is accompanied by a sudden pain, and produces a sensation as if the individual had been struck a violent blow on the part. The tendo calcaneus is also sometimes ruptured. It is stated that John Hunter ruptured his tendo calcaneus while dancing, at the age of forty. The bursa between the tendo calcaneus and the posterior surface of the calcaneus sometimes becomes inflamed, especially in pedestrians and 'long-distance' walkers. It causes great and disabling pain, and entirely prevents the sufferer from continuing his walk.

FASCIA ROUND THE ANKLE

Fibrous bands, thickened portions of fascia, bind down the tendons in front of and behind the ankle in their passage to the foot. They comprise the transverse crural, cruciate crural, and lacinate ligaments, and the superior and inferior peronæal retinacula.

The **transverse crural ligament** (upper part of anterior annular ligament) (figs. 578, 581) binds down the tendons of the Tibialis anterior, Extensor hallucis longus, Extensor digitorum longus and Peronæus tertius as they descend on the front of the tibia and fibula; the anterior tibial vessels and the deep peronæal nerve also pass under cover of it. It is attached laterally to the lower end of the fibula, and medially to the tibia; above, it is continuous with the fascia of the leg.

The **cruciate crural ligament** (lower part of anterior annular ligament) (figs. 578, 581) is a Y-shaped band placed in front of the ankle-joint. The stem of the Y is attached to the upper surface of the calcaneus, in front of the sulcus calcanei; it is directed medialwards in front of the tendons of the Peronæus tertius and Extensor digitorum longus and divides into two limbs. One limb is directed upwards and medialwards, to be attached to the tibial malleolus, passing over the Extensor hallucis longus and the anterior tibial vessels and deep peronæal nerve, but enclosing the Tibialis anterior by a splitting of its fibres. The other limb extends downwards and medialwards, to be attached to the border of the plantar aponeurosis; it crosses the tendons of the Extensor hallucis longus and Tibialis anterior, and the arteria dorsalis pedis and the terminal branches of the deep peronæal nerve.

The **lacinate ligament** (internal annular ligament) extends from the tibial malleolus above to the margin of the calcaneus below; its upper border is continuous with the deep fascia of the leg, its lower with the plantar aponeurosis and the fibres of origin of the Abductor hallucis muscle. It converts a series of bony grooves in this situation into canals for the passage of the tendons of the flexor muscles into the sole of the foot and also affords protection to the posterior tibial vessels and tibial nerve as they enter the sole of the foot. From the medial to the lateral side, these structures lie in the following order: tendon of the Tibialis posterior, tendon of the Flexor digitorum longus, posterior tibial vessels and tibial nerve, and tendon of the Flexor hallucis longus.

The **peronæal retinacula** are fibrous bands which retain the tendons of the Peronæi longus and brevis in position as they cross the lateral side of the ankle. The **superior retinaculum** (external annular ligament) is attached above to the lateral malleolus and below to the lateral surface of the calcaneus. The **inferior retinaculum** is continuous in front with the cruciate crural ligament; behind it is attached to the lateral surface of the calcaneus; some of its

fibres are fixed to the trochlear process of the calcaneus, forming a septum between the tendons of the Peronæi longus and brevis.

The mucous sheaths of the tendons round the ankle.—The tendons crossing the ankle-joint are enclosed in mucous sheaths which have an almost

FIG. 581.—The mucous sheaths of the tendons round the ankle. Lateral aspect.

FIG. 582.—The mucous sheaths of the tendons round the ankle. Medial aspect.

uniform length of about 8 cm. each. On the *front* of the ankle (fig. 581) the sheath for the Tibialis anterior extends from the upper margin of the transverse crural ligament to the interval between the diverging limbs of the cruciate ligament; those for the Extensor digitorum longus and Extensor hallucis longus reach upwards to just above the level of the malleoli, the former being the higher. The sheath of the Extensor hallucis longus is prolonged on to

the base of the first metatarsal bone, while that of the Extensor digitorum longus reaches only to the level of the base of the fifth metatarsal bone. On the *medial side* of the ankle (fig. 582) the sheath for the Tibialis posterior extends for about 4 cm. above the malleolus; below, it ends just short of the insertion of the tendon into the tuberosity of the navicular bone. The sheath for Flexor hallucis longus reaches up to the level of the malleolus, while that for the Flexor digitorum longus is slightly higher; the former is continued to the base of the first metatarsal bone, but the latter ends opposite the navicular bone.

On the *lateral side* of the ankle (fig. 581) a sheath, which is single for the greater part of its extent, encloses the Peronæi longus and brevis. It extends upwards for about 4 cm. above the tip of the malleolus and downwards and forwards for about the same distance.

IV. MUSCLES OF THE FOOT

1. DORSAL MUSCLE OF THE FOOT

Extensor digitorum brevis

The **fascia** on the dorsum of the foot (*fascia dorsalis pedis*) is a thin membranous layer, continuous above with the transverse and cruciate crural ligaments; on either side it blends with the plantar aponeurosis; anteriorly it forms a sheath for the tendons on the dorsum of the foot.

The **Extensor digitorum brevis** (figs. 578, 581) is a thin muscle, which arises from the forepart of the upper and lateral surface of the calcaneus, in front of the groove for the Peronæus brevis; from the lateral talocalcaneal ligament, and the stem of the cruciate crural ligament. It passes obliquely forwards and medialwards across the dorsum of the foot, and ends in four tendons. The medial part of the muscle is usually a more or less distinct slip ending in a tendon which crosses the dorsalis pedis artery and is inserted into the dorsal surface of the base of the first phalanx of the great toe; it is sometimes described as a separate muscle—the *Extensor hallucis brevis*. The other three tendons are inserted into the lateral sides of the tendons of the Extensor digitorum longus of the second, third, and fourth toes.

Nerves.—It is supplied by the deep peronæal nerve.

Actions.—The Extensor digitorum brevis extends the phalanges of the four toes into which it is inserted, but, in the great toe, acts only on the first phalanx.

2. PLANTAR MUSCLES OF THE FOOT

The **plantar aponeurosis** is of great strength, and consists of white fibres disposed, for the most part, longitudinally: it is divided into central, lateral, and medial portions.

The *central portion*, the thickest, is narrow behind, and attached to the medial process of the tuberosity of the calcaneus, posteriorly to the origin of the Flexor digitorum brevis; it becomes broader and thinner in front, and divides near the heads of the metatarsal bones into five processes, one for each of the toes. Each of these processes splits opposite the metatarsophalangeal articulation into two strata, superficial and deep. The superficial stratum is inserted into the skin of the transverse sulcus which separates the toes from the sole. The deep stratum divides into two slips which embrace the sides of the flexor tendons of the toes, and blend with the sheaths of the tendons, and with the transverse metatarsal ligament, thus forming a series of arches through which the tendons of the short and long flexors pass to the toes. Through the intervals between the five processes the digital vessels and nerves and the tendons of the Lumbricales are transmitted. At the point of division of the aponeurosis are numerous transverse fasciculi which bind the processes together, and connect them with the integument. The central portion of the plantar aponeurosis is continuous with the lateral and medial portions, and sends upwards into the foot, at the lines of junction, two vertical intermuscular

septa, which separate the intermediate from the lateral and medial groups of plantar muscles; from these vertical septa thinner transverse septa are derived which separate the different layers of muscles in this region. The upper surface of the central part of the aponeurosis gives origin behind to the *Flexor digitorum brevis*.

The *lateral portion* covers the under surface of the *Abductor digiti quinti*; it is thin in front and thick behind, where it forms a strong band between the lateral process of the tuberosity of the calcaneus and the base of the fifth metatarsal bone; it is continuous medially with the central portion, and laterally with the fascia dorsalis pedis.

FIG. 583.—Muscles of the sole of the foot. First layer.

The *medial portion* is thin, and covers the under surface of the *Abductor hallucis*; it is attached behind to the lacinate ligament, and is continuous medially with the fascia dorsalis pedis, and laterally with the central portion of the plantar aponeurosis.

The muscles in the plantar region of the foot may be divided into medial, lateral and intermediate groups; but for descriptive purposes it is more convenient to divide them into four layers, in the order in which they are successively exposed in dissecting this region.

First Layer (fig. 583)

Abductor hallucis.
Flexor digitorum brevis.
Abductor digiti quinti.

The *Abductor hallucis* lies along the medial border of the foot and covers the origins of the plantar vessels and nerves. It arises from the medial process of the tuberosity of the calcaneus, the lacinate ligament, the plantar aponeurosis, and the intermuscular septum between it and the *Flexor digitorum brevis*. The fibres end in a tendon which is inserted, together with the medial tendon of the *Flexor hallucis brevis*, into the medial side of the base of the first phalanx of the great toe.

The *Flexor digitorum brevis* lies immediately above the central part of the plantar aponeurosis. Its deep surface is separated from the lateral plantar vessels and nerves by a thin layer of fascia. It arises by a narrow tendon, from the medial process of the tuberosity of the calcaneus, the central part of

the plantar aponeurosis, and the intermuscular septa between it and the adjacent muscles. It divides into four tendons, one for each of the four lesser toes. Opposite the bases of the first phalanges, each tendon divides into two slips, to allow of the passage of the corresponding tendon of the *Flexor digitorum longus*; the two slips then unite and form a grooved channel for the reception of the accompanying long flexor tendon. The tendon divides again and is inserted into the sides of the second phalanx about its middle. The mode of division of the tendons of the *Flexor digitorum brevis*, and of their insertion into the phalanges, is analogous to that of the tendons of the *Flexor digitorum sublimis* in the hand.

Fibrous sheaths of the flexor tendons.—The terminal portions of the tendons of the long and short flexor muscles are contained in osseo-aponeurotic canals similar in their arrangement to those in the fingers. These canals are bounded above by the phalanges, and below by fibrous bands, which arch across the tendons, and are attached on either side to the margins of the phalanges. Opposite the bodies of the proximal and second phalanges the fibrous bands (*vaginal ligaments*) are strong, and the fibres are transverse; but opposite the joints they are much thinner, and the fibres are directed obliquely. Each canal contains a mucous sheath, which is reflected on the contained tendons; within this sheath are *vincula tendinea* arranged similarly to those of the fingers.

The **Abductor digiti quinti** lies along the lateral border of the foot, and its medial margin is in relation with the lateral plantar vessels and nerve. It arises from the lateral and medial processes of the tuberosity of the calcaneus, the under surface of the bone between the processes, the plantar aponeurosis, and the intermuscular septum between it and the *Flexor digitorum brevis*. Its tendon glides over a smooth facet on the under surface of the base of the fifth metatarsal bone and is inserted, with the *Flexor digiti quinti brevis*, into the lateral side of the base of the first phalanx of the fifth toe.

Second Layer (fig. 584)

Quadratus plantæ.

Lumbricales.

The **Quadratus plantæ** (*Flexor accessorius*) arises by two heads, which are separated from each other by the long plantar ligament: the medial, the larger, head is muscular, and is attached to the medial concave surface of the calcaneus, below the groove for the tendon of the *Flexor hallucis longus*; the lateral head, flat and tendinous, arises from the calcaneus in front of the lateral process of its tuberosity, and from the long plantar ligament. The two portions join at an acute angle, and end in a flattened band which is inserted into the surfaces and lateral margin of the tendon of the *Flexor digitorum longus*, forming a kind of groove in which the tendon is lodged. It usually sends slips to those tendons of the *Flexor digitorum longus* which pass to the second, third, and fourth toes.

The **Lumbricales** are four small muscles, accessory to the tendons of the *Flexor digitorum longus*, and numbered from the medial side of the foot; they arise from these tendons, as far back as their angles of separation, each springing from two tendons, except the first, which arises only from the medial border of the first tendon of the *Flexor digitorum longus*. The muscles end in tendons, which pass forwards on the medial sides of the four lesser toes, and are inserted into the expansions of the tendons of the *Extensor digitorum longus* on the dorsal surfaces of the first phalanges.

Third Layer (fig. 585)

Flexor hallucis brevis.

Adductor hallucis.

Flexor digiti quinti brevis.

The **Flexor hallucis brevis** arises by a pointed tendinous process from the medial part of the under surface of the cuboid bone, the contiguous portion of the third cuneiform bone, and the prolongation of the tendon of the *Tibialis posterior* which is attached to that bone. It divides into two portions, and the tendons of these are inserted into the medial and lateral sides of the base of the first phalanx of the great toe, a sesamoid bone being present in each tendon at its insertion. The medial portion is blended with the *Abductor hallucis* previous to its insertion; the lateral with the *Adductor hallucis*; the tendon of the *Flexor hallucis longus* lies in a groove between them; the lateral portion is sometimes described as the *first plantar interosseous* muscle.

The **Adductor hallucis** arises by two heads—oblique and transverse. The *oblique head* springs from the bases of the second, third, and fourth metatarsal bones, and the sheath of the tendon of the *Peroneus longus*, and is inserted, together with the lateral portion of the *Flexor hallucis brevis*, into the lateral side of the base of the first phalanx of the great toe. The *transverse*

head (*Transversus pedis*), a narrow, flat fasciculus, arises from the plantar metatarsophalangeal ligaments of the third, fourth, and fifth toes (sometimes only from the third and fourth), and from the transverse ligament of the metatarsus. It is inserted into the lateral side of the base of the first phalanx of the great toe, its tendon of insertion blending with that of the oblique head.

FIG. 584.—Muscles of the sole of the foot. Second layer.

FIG. 585.—Muscles of the sole of the foot. Third layer.

The *Flexor digiti quinti brevis* arises from the base of the fifth metatarsal bone, and the sheath of the *Peronæus longus*; its tendon is inserted into the lateral side of the base of the first phalanx of the fifth toe. Occasionally a few of the deeper fibres are inserted into the lateral part of the distal half of the fifth metatarsal bone; these are described by some as a distinct muscle, the *Opponens digiti quinti*.

Fourth Layer.

Interossei.

The *Interossei* in the foot are similar to those in the hand, but are grouped on either side of the middle line of the *second* digit, instead of that of the *third*. They consist of a dorsal and a plantar set.

The **Interossei dorsales** (fig. 586), four in number, are situated between the metatarsal bones. They are bipennate muscles, each arising by two heads from the adjacent sides of the metatarsal bones between which it is placed; their tendons are inserted into the bases of the first phalanges, and into the aponeuroses of the tendons of the *Extensor digitorum longus*. The first is inserted into the medial side of the second toe; the other three into the lateral sides of the second, third, and fourth toes. In the angular interval between the heads of each of the three lateral muscles, one of the perforating arteries passes to the dorsum of the foot; through the space between the heads of the first muscle the deep plantar branch of the *dorsalis pedis* artery enters the sole of the foot.

FIG. 586.—The *Interossei dorsales*.
Left foot.

FIG. 587.—The *Interossei plantares*.
Left foot.

The **Interossei plantares** (fig. 587), three in number, lie beneath rather than between the metatarsal bones, and each is connected with but one metatarsal bone. They arise from the bases and medial sides of the bodies of the third, fourth, and fifth metatarsal bones, and are inserted into the medial sides of the bases of the first phalanges of the same toes, and into the aponeuroses of the tendons of the *Extensor digitorum longus*.

Nerves.—The *Flexor digitorum brevis*, the *Flexor hallucis brevis*, the *Abductor hallucis*, and the first *Lumbricalis* are supplied by the medial plantar nerve; all the other muscles in the sole of the foot by the lateral plantar. The first *Interosseus dorsalis* frequently receives an extra filament from the medial branch of the deep peroneal nerve on the dorsum of the foot, and the second *Interosseus dorsalis* a twig from the lateral branch of the same nerve.

Actions.—The plantar muscles of the foot act upon the toes, and may be grouped as abductors, adductors, flexors, and extensors. The *abductors* are the *Interossei dorsales*, the *Abductor hallucis*, and the *Abductor digiti quinti*. The *Interossei dorsales* are abductors from an imaginary line passing through the axis of the second toe, so that the first muscle draws the second toe medialwards, the second muscle draws the same toe lateralwards, and the third and fourth draw the third and fourth toes lateralwards. Like the *Interossei* in the hand, they assist in flexing the first and extending the second and third phalanges. The *Abductor hallucis* abducts the great toe from the second, and also flexes its proximal phalanx. In the same way the action of the *Abductor digiti quinti* is twofold, as an abductor

MYOLOGY

of this toe from the fourth, and a flexor of its proximal phalanx. The *adductors* are the *Interossei plantares* and the *Adductor hallucis*. The *Interossei plantares* adduct the third, fourth, and fifth toes towards the imaginary line passing through the second toe, and, by means of their insertions into the aponeuroses of the *Extensor tendons*, assist in flexing the proximal phalanges and extending the middle and terminal phalanges. The oblique head of the *Adductor hallucis* is chiefly concerned in adducting the great toe, but it also assists in flexing this toe; the transverse head approximates all the toes and thus increases the curve of the transverse arch of the metatarsus. The *flexors* are the *Flexor digitorum brevis*, the *Quadratus plantæ*, the *Flexor hallucis brevis*, the *Flexor digiti quinti brevis*, and the *Lumbricales*. The *Flexor digitorum brevis* flexes the second phalanges upon the first, and, continuing its action, flexes the first phalanges also, and brings the toes together. The *Quadratus plantæ* assists the *Flexor digitorum longus* and converts the oblique

FIG. 588.—Fracture of the neck of the femur within the articular capsule.

pull of the tendons of that muscle into a direct backward pull upon the toes. The *Flexor digiti quinti brevis* flexes the little toe and draws its metatarsal bone downwards and medialwards. The *Lumbricales*, like the corresponding muscles in the hand, assist in flexing the proximal phalanges, and, by their insertions into the tendons of the *Extensor digitorum longus*, aid that muscle in extending the middle and terminal phalanges.

Applied Anatomy.—The student should now consider the effects produced by the action of the various muscles in fractures of the bones of the lower extremity. The more common forms of fracture are selected for illustration and description.

In fracture of the neck of the femur inside the articular capsule (fig. 588), the characteristic signs are slight shortening of the limb, and eversion of the foot, neither of which may appear until some time after the injury. The eversion is caused by the weight of the limb rotating it outwards. The shortening is produced by the contraction of all the muscles about the joint.

In fracture of the femur just below the trochanters (fig. 589), the upper fragment is tilted forwards almost at right angles with the pelvis, by the *Psoas major* and *Iliacus*; and, at the same time, everted and drawn laterally by the external rotator muscles and *Glutæi*, causing a marked prominence at the upper and lateral side of the thigh, and much pain from the bruising and laceration of the muscles. The limb is shortened, because the lower fragment is drawn upwards by the *Rectus femoris* in front, and the *Biceps femoris*, *Semimembranosus*, and *Semitendinosus* behind; it is, at the same time, everted. This

fracture may be reduced by relaxation of all the muscles involved, to effect which the limb should be put up with the thigh flexed on the pelvis and the leg on the thigh.

FIG. 589.—Fracture of the femur below the trochanters.

FIG. 591.—Fracture of the patella.

FIG. 592.—Oblique fracture of the body of the tibia.

FIG. 590.—Fracture of the femur above the condyles.

Oblique fracture of the femur *immediately above the condyles* (fig. 590) is a formidable injury, and attended with considerable displacement. On examination of the limb,

the lower fragment may be felt deep in the popliteal fossa, being drawn backwards by the Gastrocnemius, and upwards by the hamstrings and Rectus femoris. The pointed end of the upper fragment is drawn medialwards by the Pectineus and Adductors, and tilted forwards by the Psoas major and Iliacus, piercing the Rectus, and occasionally the integument. Relaxation of these muscles, and direct approximation of the broken fragments, are effected by traction with the limb fully flexed. The greatest care is requisite in keeping the pointed extremity of the upper fragment in proper position; otherwise, after union of the fracture, the power of extension of the limb is partially destroyed, the Rectus femoris being held down by the fractured end of the bone.

In transverse fracture of the *patella* (fig. 591) the fragments are separated by the action of the Quadriceps femoris and by the effusion which takes place into the joint; the extent of separation of the two fragments depending upon the degree of laceration of the ligamentous structures around the bone.

Oblique fracture of the *body of the tibia* (fig. 592). If the fracture takes place obliquely from above, downwards and forwards, the fragments ride over one another, the lower fragment being drawn backwards and upwards by the powerful action of the muscles of the calf; the pointed extremity of the upper fragment projects forwards immediately beneath the integument, often protruding through it, and rendering the fracture compound. If the direction of the fracture is the reverse of that shown in the figure, the pointed extremity of the lower fragment projects forwards, rising up on the lower end of the upper one. By bending the knee, which relaxes the opposing muscles, and making extension from the ankle and counter-extension at the knee, the fragments may be brought into apposition. It is sometimes necessary, however, in compound fracture to remove a portion of the projecting bone with the saw before complete adaptation can be effected.

Fracture of the *fibula with dislocation of the foot lateralwards*, commonly known as 'Pott's fracture,' is one of the most frequent injuries in the region of the ankle-joint. The fibula is fractured about 7 or 8 cm. above the ankle; in addition to this the medial malleolus is broken off, or the deltoid ligament torn through, and the talus displaced from the corresponding surface of the tibia. The foot is markedly everted, and the sharp edge of the upper end of the fractured malleolus presses strongly against the skin; at the same time, the heel is drawn up by the muscles of the calf. This injury can generally be reduced by flexing the leg at right angles with the thigh, which relaxes all the opposing muscles, and by making extension from the ankle and counter-extension at the knee. There is later a great tendency for the foot to fall backwards at the ankle-joint, and constant supervision is required to counteract this.

ANGIOLOGY

THE vascular system is divided for descriptive purposes into (a) the *blood vascular system*, comprising the heart and blood-vessels through which the blood circulates ; * and (b) the *lymph vascular system*, consisting of lymph glands and lymphatic vessels, through which a colourless fluid, the lymph, circulates. The two systems communicate with each other and are intimately associated developmentally.

The heart, the central organ of the blood vascular system, is a hollow muscle ; by its contraction the blood is pumped to all parts of the body through a complicated series of tubes, termed *arteries*. The arteries undergo enormous ramification in their course throughout the body, and end in minute vessels, called *arterioles*, which open into a close-meshed network of microscopic vessels, termed *capillaries*. After the blood has passed through the capillaries it is collected into a series of vessels, called *veins* ; these unite with one another, and ultimately two large veins, named the superior and inferior venæ cavæ, are formed which return the blood to the heart. The passage of the blood through the heart and blood-vessels is termed the *circulation* of the blood, of which the following is an outline.

The heart is divided into right and left halves, and each half is subdivided into two cavities, an atrium and a ventricle, which communicate freely with one another ; the atria are receiving chambers and the ventricles distributing ones. The right atrium and right ventricle form the right half, and the left atrium and left ventricle the left half of the heart ; the right half contains venous or impure blood ; the left, arterial or pure blood. From the cavity of the left ventricle the pure blood is carried into a large artery, the aorta, through the numerous branches of which it is distributed to all parts of the body, with the exception of the lungs. As the blood traverses the capillaries of the body it gives up to the tissues the materials necessary for their growth and nourishment, and receives from the tissues the waste products resulting from their metabolism. In doing so it is changed from arterial into venous blood, which is collected by the veins and returned by them to the right atrium of the heart. From this cavity the venous blood passes into the right ventricle, and from it is conveyed through the pulmonary arteries to the lungs, where it becomes arterialised, and is carried thence to the left atrium by the pulmonary veins. From the left atrium it passes into the left ventricle, from which the cycle once more begins.

The course of the blood from the left ventricle through the body generally to the right side of the heart constitutes the greater or *systemic* circulation, while its passage from the right ventricle through the lungs to the left side of the heart is termed the lesser or *pulmonary* circulation.

It is necessary, however, to state that the blood which circulates through the spleen, pancreas, stomach, small intestine, and the greater part of the large intestine is not returned directly from these organs to the heart, but is conveyed by the *portal vein* to the liver. In the liver this vein divides like an artery, and ultimately ends in capillary-like vessels (*sinusoids*), from which the rootlets of the *hepatic veins* arise ; the hepatic veins carry the blood into the inferior vena cava, whence it is conveyed to the right atrium. From this it will be understood that the blood supplied to the above-named viscera passes through two sets of vessels before reaching the inferior vena cava : (1) the

*The blood is described on pp. 26 to 29.

capillaries in the spleen, pancreas, stomach, &c., draining into the portal vein and (2) the sinusoids in the liver, draining into the hepatic veins.

Structure of arteries (fig. 593).—The wall of an artery consists of three coats, an internal or *tunica intima*, a middle or *tunica media*, and an external or *tunica adventitia*. The external coat is tougher than the other two, which are ruptured when a ligature is tied round the vessel, and, in virtue of their elasticity, become retracted from the site of the ligature.

The *tunica intima* consists of (a) an internal layer of flattened cells, (b), beneath these, a small quantity of loose connective tissue, and (c) an elastic lamina. The flattened or endothelial cells are fusiform in shape with the long axis of each in the long axis of the blood-vessel. Each cell possesses a nucleus, and is attached to adjacent cells by cement-substance which reduces silver nitrate. The connective

FIG. 593.—Transverse section through a small artery and vein of the mucous membrane of the epiglottis of a child. $\times 350$. (Klein and Noble Smith.)

A. Artery, showing the nucleated endothelium, *e*, which lines it; the vessel being contracted, the endothelial cells appear very thick. Outside the endothelium is the wavy elastic lamina. The chief part of the wall of the vessel is occupied by the circular muscular coat *m*: the rod-shaped nuclei of the muscle-cells are well seen; *a*, part of the adventitia which gradually merges into the surrounding connective tissue. V. Vein showing a thin endothelial membrane, *e*, raised accidentally from the intima, which on account of its delicacy is seen as a mere line on the media *m*. This latter is composed of a few smooth muscle-cells. *a*. The adventitia, similar in structure to that of an artery.

tissue layer is very thin, and contains branched cells, and, in the larger arteries, fine elastic fibres. The elastic lamina is built up of longitudinally arranged elastic fibres fused together, and is usually fenestrated, having round or oval apertures at irregular intervals. In a transverse section of an artery it appears as a characteristic wavy line, owing to the contracted condition of the empty vessel.

The *tunica media*, in the smaller and medium-sized arteries, consists principally of smooth muscular fibres arranged circularly round the vessel; the fibres have well-marked, rod-shaped nuclei. In the smallest arteries the middle coat is entirely composed of smooth muscular fibres (fig. 594). In medium-sized arteries (fig. 595) there are in addition elastic fibres and fine elastic membranes lying between the layers of muscular fibres. In the larger arteries, as the iliac and carotid, the proportion of elastic tissue is greatly increased, and in the aorta relatively thick elastic laminae form the greater part of the thickness of the middle coat.

The *tunica adventitia* consists mainly of fine and closely felted bundles of white connective tissue; in all but the smallest arteries it contains some elastic fibres. The elastic tissue is most abundant next the tunica media, and it is sometimes described as forming here, between the adventitia and media, a special layer, the *tunica elastica externa* of Henle; this layer is most marked in arteries of medium size. In the largest vessels the external coat is relatively thin, but in small

arteries it is of greater proportionate thickness. In the smaller arteries it consists of a single layer of white connective tissue and elastic fibres; in the smallest arteries the elastic fibres are wanting, and the connective tissue, of which the coat is composed, becomes more homogeneous the nearer it approaches the capillaries, and is gradually reduced to a thin membranous envelope, which finally disappears.

Some arteries have extremely thin walls in proportion to their size; this is especially the case in those situated within the cranium and vertebral canal, and depends on the thinness of the external and middle coats.

The arteries, in their distribution throughout the body, are enclosed in thin fibro-areolar investments, which form their *sheaths*. The vessel is loosely connected with its sheath by delicate areolar tissue; and the sheath usually encloses the accompanying veins, and sometimes a nerve. Some arteries, as those in the cranium, are devoid of sheaths.

The larger arteries are supplied with blood-vessels. These nutrient vessels, called the *vasa vasorum*, arise from branches of the artery itself, or of a neighbouring vessel, at some considerable distance from the points at which they are distributed; they ramify in the loose areolar tissue connecting the artery with its sheath, and are distributed to the external coat; in man they do not penetrate the other coats; but in some of the larger mammals a few vessels have been traced into the middle coat. Minute veins return the blood from these vessels; they empty themselves into the vein or veins accompanying the artery. Lymphatic vessels are also present in the outer coat.

Arteries are also supplied with nerves, which form intricate plexuses upon the surfaces of the larger trunks, and run along the smaller arteries as single filaments, or bundles of filaments. Most of the nerve-fibres are non-medullated, and are derived from the sympathetic system, but some are medullated. The non-medullated fibres are, for the most part, efferent, and have their terminations in the middle coat. The medullated fibres are believed to be afferent and are distributed to the outer and inner coats. Pacinian corpuscles are occasionally found in the outer coat of the aorta.

FIG. 594.—Small artery and vein, from pia mater of sheep. $\times 250$.

Surface view above the interrupted line; longitudinal section below. Artery in red; vein in blue.

FIG. 595.—Transverse section of femoral artery of dog. $\times 250$.

The capillaries.—The smaller arterial branches (excepting those of the cavernous structure of the sexual organs, of the splenic pulp, and of the placenta) subdivide,

giving rise to minute vessels termed capillaries. These are interposed between the smallest branches of the arteries and the commencing veins, constituting a network, the branches of which maintain the same diameter throughout; the meshes of the network are more uniform in shape and size than those formed by the anastomoses of the small arteries and veins.

The *diameters* of the capillaries vary in the different tissues of the body, the usual size being about $8\ \mu$. The smallest are those of the brain and the mucous membrane of the intestines; and the largest those of the skin and the marrow of bone, where they are stated to be as large as $20\ \mu$ in diameter.

The *form* of the capillary net varies in the different tissues, the meshes being generally rounded or elongated. Rounded meshes are most common, and prevail where there is a dense network, as in the lungs, in most glands and mucous membranes, and in the cutis; the meshes are not of an absolutely circular outline, but more or less angular. Elongated meshes are observed in the muscles and nerves, the meshes resembling parallelograms in form, the long axis of the mesh running parallel with the long axis of the muscle or nerve. Sometimes the capillaries have a looped arrangement; a single vessel projecting from the common network and returning after forming one or more loops, as in the papillæ of the tongue and skin.

The number of the capillaries and the size of the meshes determine the degree of vascularity of a part; the closest network and the smallest interspaces are found in the lungs and in the chorioid coat of the eye. As a general rule, the more active the function of the organ, the closer is its capillary net and the larger its supply of blood. Blood-vessels are few in number in tendons, in which very little organic change occurs after their formation.

Structure.—The wall of a capillary consists of flattened cells joined edge to edge by cement-substance, and continuous with the endothelial cells which line

FIG. 596.—Capillaries from the mesentery of a guinea-pig, after treatment with solution of nitrate of silver.

a. Cells. b. Their nuclei.

the arteries and veins. When stained with nitrate of silver the edges which bound the epithelial cells are brought into view (fig. 596). These cells are of large size and of an irregular polygonal or lanceolate shape, each containing an oval nucleus which may be displayed by carmine or hæmatoxylin. Between their edges, at various points of their meeting, roundish dark spots are sometimes seen, which have been described as stomata, though they are closed by intercellular substance. By some they are believed to be the situations through which the colourless corpuscles of the blood, when migrating from the blood-vessels, emerge; but this view is not universally accepted.

In developing capillaries, and in the capillaries of the glomeruli of the kidneys, the intestinal villi, and the chorioid coat of the eye, intercellular cement cannot be demonstrated, and the cells are believed to form a syncytium.

In many situations a delicate sheath or envelope of branched nucleated connective tissue cells is found around the simple capillary tube, particularly the larger ones; and in other places, especially in the glands, the capillaries are invested with retiform connective tissue.

Sinusoids.—In the heart, the liver, the supra-renal and parathyroid glands, the glomera carotica and glomus coccygeum, the smallest blood-vessels present various differences from true capillaries. They are wider, with an irregular lumen, and have no connective tissue covering, their endothelial cells being in direct contact with the cells of the organ. Moreover, they are either arterial or venous and not intermediate as are the true capillaries. These vessels have been called *sinusoids* by Minot. They are formed by columns of cells or trabeculae pushing their way into a large blood-vessel or blood-space and carrying its endothelium before them; at the same time the wall of the vessel or space grows out between the cell columns.

Structure of veins.—The walls of the veins, like those of the arteries, are composed of three coats—internal, middle, and external; and these are, with the necessary modifications, analogous to the coats of the arteries; the internal being the endothelial, the middle the muscular, and the external the connective tissue or areolar (fig. 593). The main difference between the veins and the arteries is in the comparative weakness of the middle coat in the former.

In the smallest veins the three coats are hardly to be distinguished (fig. 594). The endothelium is supported on a membrane separable into two layers, the outer of which is the thicker, and consists of a delicate, nucleated membrane (*tunica adventitia*), while the inner is composed of a network of longitudinal elastic fibres (*tunica media*). In the veins next above these in size (0.4 mm. in diameter), a connective tissue layer containing numerous smooth muscular fibres circularly disposed can be traced, forming the middle coat, while the elastic and connective tissue elements of the outer coat are more distinctly perceptible. In the middle-sized veins (fig. 597) the typical structure of these vessels becomes clear. The endothelium is of the same character as in the arteries, but its cells are shorter and

FIG. 597.—Transverse section of femoral vein of dog. $\times 250$. (Vein accompanying artery shown in fig. 595.) Elastic tissue is not differentiated in this preparation.

broad. It is supported by a connective tissue layer, consisting of a delicate network of branched cells, and external to this is a layer of elastic fibres disposed in the form of a network in place of the definite fenestrated membrane seen in arteries. This constitutes the *tunica intima*. The *tunica media* is composed of a thick layer of connective tissue with elastic fibres, intermixed, in some veins, with a layer of smooth muscular fibres arranged circularly. The white fibres are in considerable excess, and the elastic fibres are in much smaller proportion in the veins than in the arteries. The *tunica adventitia* consists, as in the arteries, of areolar tissue, with longitudinal elastic fibres. In the largest veins it is from two to five times thicker than the *tunica media*, and contains a large number of longitudinal muscular fibres. These are most distinct in the inferior vena cava, especially at the termination of this vein in the heart, in the trunks of the hepatic veins, in all the large trunks of the portal vein, and in the external iliac, renal, and azygos veins. In the inferior vena cava, renal and portal veins they extend through the whole thickness of the outer coat, but in the other veins mentioned a layer of connective and elastic tissue is found external to the muscular fibres. The large veins which open into the heart are covered for a short distance with a layer of striped muscular tissue continued on to them from the heart. Muscular tissue is wanting—(1) in the veins of the maternal part of the placenta; (2) in the venous sinuses of the dura mater and the veins of the pia mater; (3) in the veins of the retina; (4) in the veins of the spongy substance of bones; (5) in the venous spaces of the corpora cavernosa. The veins of the above-mentioned parts consist of an endothelial lining supported on one or more layers of areolar tissue.

Most veins are provided with *valves* which serve to prevent the reflux of the blood. Each valve is formed by a reduplication of the inner coat, strengthened by connective tissue and elastic fibres, and is covered on both surfaces by endothelium, the arrangement of which differs on the two surfaces. On the surface of the valve next the wall of the vein, the cells are arranged transversely; while on the other surface, over which the current of blood flows, the cells are arranged longitudinally in the direction of the current. Most commonly two such valves are found placed opposite one another, more especially in the smaller veins or in the larger trunks at the point where they are joined by smaller branches; occasionally there are three and sometimes only one. The valves are semilunar. They are attached by their convex edges to the wall of the vein; the concave margins are free, directed in the course of the venous current, and lie in close apposition with the wall of the vein as long as the current of blood takes its natural course; if, however, any regurgitation takes place, the valves become distended, their opposed edges are brought into contact, and the current is interrupted. The wall of the vein on the cardiac side of the attachment of each valve is expanded into a pouch or sinus, which gives to the vessel, when injected or distended with blood, a knotted appearance. The valves are very numerous in the veins of the extremities, especially in the veins of the lower extremities, these vessels having to conduct the blood against the force of gravity. They are absent in the very small veins, i.e. those less than 2 mm. in diameter, also in the *venæ cavæ*, hepatic, renal, uterine, and ovarian veins. A few valves are found in each testicular vein, and one also at its point of junction with the renal vein or inferior vena cava respectively. The cerebral and spinal veins, the veins of the cancellated tissue of bone, the pulmonary veins, and the umbilical vein and its branches, are destitute of valves. A few valves are occasionally found in the azygos and intercostal veins. Valves are present in the tributaries of the portal vein in the foetus and for a short time after birth; as a rule they soon atrophy and disappear, but sometimes they persist in a degenerate form.

The veins, like the arteries, are supplied with nutrient vessels, *vasa vasorum*. Nerves also are distributed to them in the same manner as to the arteries, but in much less abundance.

THE THORACIC CAVITY

The heart and lungs are situated in the thorax, the walls of which afford them protection. The heart lies between the two lungs, and is enclosed within a fibrous bag, the *pericardium*, while each lung is invested by a serous membrane, the *pleura*. The skeleton of the thorax, and the shape and boundaries of the cavity, have already been described (p. 190).

The cavity of the thorax.—The capacity of the thoracic cavity does not correspond with its apparent size externally, because (1) the space enclosed by the lower ribs is occupied by some of the abdominal viscera; and (2) the cavity extends for a short distance into the neck above the anterior parts of the first ribs. The size of the thoracic cavity is constantly varying during life with the movements of the ribs and Diaphragm, and with the degree of distention of the abdominal viscera.

The upper opening of the thorax.—The parts which pass through the upper opening of the thorax are, from before backwards in or near the middle line, the Sternohyoideus and Sternothyreoides muscles, the remains of the thymus, the inferior thyroid veins, the trachea, œsophagus, thoracic duct, and the Longus colli muscles; laterally the innominate veins, the innominate artery, the left common carotid and left subclavian arteries, the internal mammary arteries and the costocervical trunks, the vagus, cardiac, phrenic, and sympathetic nerves, the greater parts of the anterior divisions of the first thoracic nerves, and the left recurrent nerve. The apex of each lung, covered by the pleura, also projects through this aperture, a little above the level of the sternal end of the first rib.

The lower opening of the thorax is wider transversely than from before backwards. It slopes obliquely downwards and backwards, so that the thoracic cavity is much deeper behind than in front. The Diaphragm (see p. 452) closes the opening and forms the floor of the thorax. The floor is flatter at the centre than at the sides, and higher on the right side than on the

THE PERICARDIUM

51

left; in the dead body the right side reaches the level of the upper border of the fifth costal cartilage, while the left extends only to the corresponding part of the sixth costal cartilage. From the highest point on either side the floor slopes suddenly downwards to the costal and vertebral attachments of the Diaphragm; this slope is more marked behind than in front, so that only a narrow space is left between the Diaphragm and the posterior wall of the thorax.

THE PERICARDIUM

The pericardium (fig. 598) is a conical fibroserous sac, in which the heart and the roots of the great vessels are contained. It is placed in the mediastinal cavity, behind the sternum and the cartilages of the third, fourth, fifth, sixth, and seventh ribs of the left side, and in front of the thoracic vertebrae, from the fifth to the eighth inclusive.

In *front*, it is separated from the anterior wall of the thorax, in the greater part of its extent, by the lungs and pleuræ; but a small area, somewhat variable in size, and usually corresponding with the left half of the lower part of the body of the sternum, and the sternal ends of the cartilages of the fourth and fifth ribs of the left side, comes into direct relationship with the chest-wall. Until puberty or adolescence the lower end of the thymus is in contact with the front of the upper part of the pericardium. *Behind*, the pericardium rests upon the bronchi, the œsophagus, the descending thoracic aorta, and the posterior part of the mediastinal surface of each lung. *Laterally*, it is covered by the pleuræ, and is in relation with the mediastinal surfaces of the lungs; the phrenic nerve, with its accompanying vessels, descends between the pericardium and pleura on either side.

Structure of the pericardium—Although the pericardium is usually described as a single sac, an examination of its structure shows that it consists essentially of two sacs intimately connected with one another, but totally different in structure. The outer sac, known as the *fibrous pericardium*, consists of fibrous tissue. The inner sac, or *serous pericardium*, is a delicate membrane which lies within the fibrous sac and lines its walls; it is composed of a single layer of flattened cells resting on loose connective tissue. The heart invaginates the wall of the serous sac from above and behind, and practically obliterates its cavity, the space being a potential one.

The *fibrous pericardium* forms a flask-shaped bag, the neck of which is closed by its continuity with the external coats of the great vessels, while its base is attached to the central tendon and to the muscular fibres of the left half of the Diaphragm. (In some of the lower mammals the base is either completely separated from the Diaphragm or joined to it by some loose areolar tissue; in man much of its diaphragmatic attachment consists of loose fibrous tissue which can be readily broken down, but over a small area the central tendon of the Diaphragm and the pericardium are fused.) Above, the fibrous pericardium not only blends with the external coats of the great vessels, but is continuous with the pretracheal layer of the deep cervical fascia. By means of these upper and lower connexions it is securely anchored within the thoracic cavity. It is also attached to the posterior surface of the sternum by the *superior* and *inferior sternopericardial ligaments*; the superior passing to the manubrium, and the inferior to the xiphoid process.

The vessels receiving prolongations from the fibrous pericardium are: the aorta, the superior vena cava, the right and left pulmonary arteries, and the four pulmonary veins. The inferior vena cava enters the pericardium through the central tendon of the Diaphragm, and receives no covering from the fibrous layer.

The *serous pericardium* is, as already stated, a closed sac which lines the fibrous pericardium and is invaginated by the heart; it therefore consists of a *visceral* and a *parietal* portion. The visceral portion, or *epicardium*, covers the heart and the great vessels, and from the latter is continuous with the parietal layer which lines the fibrous pericardium. The portion which covers the vessels is arranged in the form of two tubes. The aorta and pulmonary artery are enclosed in one tube, the *arterial mesocardium*. The superior and inferior vena cava and the four pulmonary veins are enclosed in a second

tube, the *venous mesocardium*, the attachment of which to the parietal layer presents the shape of an inverted U. The cul-de-sac enclosed between the limbs of the \cap lies behind the left atrium and is known as the *oblique sinus*, while the passage between the venous and arterial mesocardia—i.e. between the aorta and pulmonary artery in front and the atria behind—is termed the *transverse sinus*.

FIG. 598.—Posterior wall of the pericardial sac, showing the lines of reflection of the serous pericardium on the great vessels.

The ligament of the left vena cava.—Between the left pulmonary artery and subjacent pulmonary vein is a triangular fold of the serous pericardium, known as the *ligament of the left vena cava* (vestigial fold of Marshall). It is formed by the duplicature of the serous layer over the remnant of the lower part of the left superior vena cava (duct of Cuvier). This vein becomes obliterated during foetal life, and remains as a fibrous band stretching from the left superior intercostal vein to the left atrium, where it is continuous with a small vein, the *vein of the left atrium* (oblique vein of Marshall), which opens into the coronary sinus.

The arteries of the pericardium are derived from the internal mammary arteries and their musculophrenic branches, and from the descending thoracic aorta; its nerves are derived from the vagus and phrenic nerves, and the sympathetic trunks.

Applied Anatomy.—Effusion of fluid into the pericardial sac often occurs in acute rheumatism or pneumonia, or in patients with chronic vascular and renal disease, embarrassing the heart's action and giving rise to signs of cardiac distress, such as pallor, a rapid and feeble pulse, dyspnoea, and restlessness. On examination, the apical cardiac impulse is absent, or replaced by a more extensive indefinite and wavering pulsation; it may appear to be in the second, third, or fourth left space, and is then not an apex-impulse, as Potain has stated, but due to the impact of some portion of the heart-wall nearer its base. In children the precordial intercostal spaces may bulge outwards. The most striking sign, however, is the great increase in all directions of the precordial dulness on percussion. This becomes pear-shaped, the stalk of the pear reaching up to about the left sternoclavicular articulation; the dulness also extends some distance to the right of the sternum, particularly in the fifth interspace (Rotch). The fluid collects mainly on either side of the heart, and below it, especially on the left side, where the Diaphragm can yield more readily to pressure than it can on the right. Ewart has drawn attention to the presence of a square patch of dulness over the base of the left lung behind, reaching up to the level of the ninth or tenth rib, and extending laterally as far as the inferior angle of the scapula; the underlying lung-tissue gives the physical signs of compression or collapse.

Paracentesis of the pericardium and withdrawal of the fluid or pus within it, in cases of rheumatic fever or pneumonia, is sometimes necessary to relieve embarrassment of the heart's action. The puncture may be made in the fifth or sixth left intercostal space near the sternum, with care to avoid wounding the internal mammary artery that usually runs 1.25 cm. lateral to the sternal edge. Alternatively the exploring needle may be entered at the left costophrenoid angle, and passed upwards and backwards into the pericardial sac. Curschmann* recommends paracentesis in or lateral to the left mamillary line in the fifth or sixth left interspace, in view of the fact that the fluid tends to collect on either side of and below the heart rather than in front of it.

Pericardiotomy is required when the effusion is of a purulent nature. In this operation a portion of the fifth or sixth costal cartilage is excised. An incision is made along the left border of the sternum from the upper border of the fourth cartilage to the seventh. The fifth costal cartilage is now separated from the sternum and raised, the tissues beneath it being peeled off, so as to avoid wounding the internal mammary artery or the pleura. The fibres of the Transversus thoracis are then separated close to the sternum, and the pericardium felt for and opened, the finger guarding the pleura and left internal mammary artery.

THE HEART (CON)

The heart is a hollow muscular organ of a somewhat conical form; it lies between the lungs in the middle mediastinum and is enclosed in the pericardium (fig. 599). It is placed obliquely in the chest behind the body of the sternum and adjoining parts of the rib cartilages, and projects farther into the left than into the right half of the thoracic cavity, so that about one-third of it is situated on the right and two-thirds on the left of the median plane.

Size.—The heart of the adult measures about 12 cm. from base to apex, 8 to 9 cm. transversely at the broadest part, and 6 cm. anteroposteriorly. Its weight, in the male, varies from 280 to 340 grammes; in the female, from 230 to 280 grammes. It continues to increase in weight and size up to an advanced period of life: this increase is more marked in men than in women.

Component parts.—As already stated (p. 545), the heart is divided into four chambers, viz. right and left atria, and right and left ventricles, the division being indicated on the surface of the heart by grooves or sulci. The atria are separated from the ventricles by the *coronary sulcus* (auriculoventricular groove); this contains the trunks of the coronary vessels of the heart, and is deficient in front, where it is crossed by the root of the pulmonary artery. The *interatrial groove*, separating the two atria, is scarcely marked on the posterior surface, while anteriorly it is hidden by the pulmonary artery and aorta. The ventricles are separated by two grooves, one of which, the *anterior longitudinal sulcus*, is situated on the sternocostal surface of the heart, near its left margin, the other, the *posterior longitudinal sulcus*, on the diaphragmatic surface near the right margin; these grooves extend from the base of the ventricular portion to a notch, the *incisura apicis cordis*, on the acute margin of the heart just to the right of the apex.

The base (fig. 600) looks upwards, backwards, and to the right, and is separated from the fifth, sixth, seventh, and eighth thoracic vertebrae by the pericardium, oesophagus, aorta, and thoracic duct. It is formed mainly by

* *Therapie der Gegenwart*, 1905.

the left atrium, and, to a small extent, by the back part of the right atrium. Somewhat quadrilateral in form, it is in relation above with the bifurcation of the pulmonary artery, and is bounded below by the posterior part of the coronary sulcus, containing the coronary sinus. On the right it is limited by the sulcus terminalis of the right atrium, and on the left by the ligament of the left vena cava and the oblique vein of the left atrium. The four pulmonary veins, two on either side, open into the left atrium, whilst the superior vena cava opens into the upper part, and the inferior vena cava into the lower part, of the right atrium.

The *apex* is directed downwards, forwards, and to the left, and is overlapped by the left lung and pleura: it lies behind the fifth left intercostal space,

FIG. 599.—Front view of the heart and lungs.

8 to 9 cm. from the mid-sternal line, or, in the male, about 4 cm. below and 2 cm. to the medial side of the left mammary papilla.

The *sternocostal surface* (fig. 601) is directed forwards, upwards, and to the left. Its lower part, formed chiefly by the right ventricle, is convex, and is traversed near its left margin by the anterior longitudinal sulcus. Its upper part, formed by the atria, is separated from the lower by the coronary sulcus; it presents a deep concavity (fig. 603) which is occupied by the ascending aorta and the pulmonary artery.

The *diaphragmatic surface* (fig. 600), directed downwards and slightly backwards, is formed by the ventricles (chiefly by the left ventricle), and rests upon the central tendon and a small part of the left muscular portion of the Diaphragm. It is separated from the base by the posterior part of the coronary sulcus, and is traversed obliquely by the posterior longitudinal sulcus.

The *right margin* of the heart, formed by the right atrium, is rounded and almost vertical; it is situated behind the third, fourth, and fifth right costal cartilages about 1.25 cm. from the margin of the sternum.

The *inferior or acute margin*, formed by the right ventricle, is nearly horizontal, and extends from the sternal end of the sixth right costal cartilage to the apex of the heart.

The *left or obtuse margin* is full and rounded; it is formed mainly by the left ventricle, but to a slight extent, above, by the left atrium. It extends from a point in the second left intercostal space, about 2.5 cm. from the sternal margin, obliquely downwards, with a convexity to the left, to the apex of the heart.

The *right atrium* is larger than the left, but its walls are somewhat thinner, measuring about 2 mm.; its cavity is capable of containing about 57 c.c. of blood. It consists of two parts: a principal cavity, or *sinus venarum*, situated posteriorly, and an anterior, smaller portion, the *auricula*.

FIG. 600.—The base and diaphragmatic surface of the heart.

The *sinus venarum* is the large quadrangular cavity placed between the two venæ cavæ. Its walls, which are extremely thin, are connected below with the right ventricle, and medially with the left atrium, but are free in the rest of their extent.

The *auricula* is a small, conical, muscular pouch, the margins of which present a dentated edge. It projects from the upper and front part of the sinus forwards and towards the left side, overlapping the root of the aorta.

The separation of the auricula from the sinus venarum is indicated externally by a groove, the *sulcus terminalis*, which extends from the front of the superior vena cava to the front of the inferior vena cava, and represents the line of union of the sinus venosus of the embryo with the primitive atrium. On the inner wall of the atrium the separation is marked by a vertical, smooth, muscular ridge, the *crista terminalis*. Behind the crest the internal surface of the atrium is smooth, while in front of it the muscular fibres of the wall are raised into parallel ridges resembling the teeth of a comb, and hence named the *musculi pectinati*.

The interior of the right atrium (fig. 602) presents the following parts for examination :

Orifices	Superior vena cava.	Valves	Valve of the inferior vena cava.
	Inferior vena cava.		Valve of the coronary sinus.
	Coronary sinus.		
	Foramina venarum minimarum.		
	Right atrioventricular.		
	Fossa ovalis.		
	Limbus fossæ ovalis.		
	Intervenous tubercle.		
	Musculi pectinati.		
	Crista terminalis.		

The *superior vena cava* returns the blood from the upper half of the body, and opens into the upper and posterior part of the atrium, the direction of its orifice being downwards and forwards. Its orifice has no valve.

FIG. 601.—Sternocostal surface of heart.

The *inferior vena cava*, larger than the superior, returns the blood from the lower half of the body, and opens into the lowest part of the atrium near the atrial septum; its orifice, directed upwards and backwards, is guarded by a rudimentary valve, the *valve of the inferior vena cava* (valve of Eustachius). The blood entering the atrium through the superior vena cava is directed downwards and forwards towards the atrioventricular orifice, whilst that entering through the inferior vena cava is directed upwards and backwards towards the atrial septum. This is the normal direction of the two currents in fetal life.

The *coronary sinus* opens into the atrium, between the orifice of the inferior vena cava and the atrioventricular opening. It returns blood from the substance of the heart, and is protected by a semicircular valve, the *valve of the coronary sinus* (valve of Thebesius).

The *foramina venarum minimarum* are the orifices of minute veins (*venæ cordis minimæ*), which return blood directly from the muscular substance of the heart.

The *right atrioventricular orifice* is the large aperture of communication between the atrium and the ventricle; it will be described with the right ventricle.

The *valve of the inferior vena cava* is situated in front of the orifice of the inferior vena cava. It is semilunar in form, its convex margin being attached to the anterior margin of the orifice; its concave margin, which is free, ends in two cornua, of which the left is continuous with the anterior edge of the *limbus fossæ ovalis* while the right is lost on the wall of the atrium. The valve is formed by a duplicature of the lining membrane of the atrium, containing a few muscular fibres. In the *fœtus* this valve is of large size, and serves to direct the blood from the inferior vena cava, through the *foramen ovale*, into the left atrium. In the *adult* it occasionally persists, and may assist in preventing the reflux of blood into the inferior vena cava; more commonly it is small, and may present a cribriform or filamentous appearance; sometimes it is altogether wanting.

FIG. 602.—Interior of right side of heart.

The *valve of the coronary sinus* is a semicircular fold of the lining membrane of the atrium, at the orifice of the coronary sinus. It prevents the regurgitation of blood into the sinus during the contraction of the atrium. This valve may be double or it may be cribriform.

The *fossa ovalis* is an oval depression on the septal wall of the atrium, and corresponds to the situation of the *foramen ovale* in the *fœtus*. It is situated at the lower part of the septum, above and to the left of the orifice of the inferior vena cava.

The *limbus fossæ ovalis* (*annulus ovalis*) is the prominent margin of the *fossa ovalis*. It is most distinct above and at the sides of the fossa; below, it is deficient. A small slit-like valvular opening is occasionally found, at the upper margin of the fossa, leading upwards, beneath the limbus, into the left atrium; it is the remains of the foetal aperture between the two atria.

The *intervenous tubercle* (*tubercle of Lower*) is a small projection on the posterior wall of the atrium, above the *fossa ovalis*. It is distinct in the hearts of quadrupeds, but in man is scarcely visible. During foetal life it may direct the blood from the superior vena cava towards the atrioventricular opening.

The **right ventricle** is triangular in form, and extends from the right atrium to near the apex of the heart. Its anterosuperior surface is rounded and convex, and forms the larger part of the sternocostal surface of the heart. Its under surface is flattened, rests upon the Diaphragm, and forms a small part of the diaphragmatic surface of the heart. Its posterior wall is formed by the ventricular septum, which bulges into the right ventricle, so that a transverse section of the cavity presents a semilunar outline. Its upper left angle forms a conical pouch, the *conus arteriosus*, from which the pulmonary artery arises. A tendinous band, which may be named the *tendon of the conus arteriosus*, extends upwards from the right atrioventricular fibrous ring (p. 562) and connects the posterior surface of the conus arteriosus to the aorta. The wall of the right ventricle is thinner than that of the left, the proportion between them being as 1 to 3; it is thickest at the base, and gradually becomes thinner towards the apex. The cavity equals in size that of the left ventricle, and is capable of holding about 85 c.c. of blood.

FIG. 603.—The heart, seen from above.

Its interior (fig. 602) presents the following parts for examination :

Orifices { Right atrioventricular.
Pulmonary artery.
Trabeculae carneae.

Valves { Tricuspid.
Pulmonary.
Chordae tendineae.

The **right atrioventricular orifice** is the large oval aperture of communication between the right atrium and ventricle. Situated at the base of the ventricle, it measures about 4 cm. in diameter and is encircled by a fibrous ring, covered by the lining membrane of the heart; it is considerably larger than the left atrioventricular orifice, being sufficient to admit the ends of four fingers. It is guarded by the tricuspid valve.

The **orifice of the pulmonary artery** is circular in form, and situated at the summit of the conus arteriosus, close to the ventricular septum. It is placed above and to the left of the atrioventricular opening, and is guarded by the pulmonary semilunar valves.

The **tricuspid valve** (figs. 602, 604) consists of three somewhat triangular cusps or segments. The largest cusp is interposed between the atrioventricular orifice and the conus arteriosus, and is termed the anterior cusp. A second, the posterior cusp, is in relation to the right margin of the ventricle, and a third, the medial cusp, to the ventricular septum. They are formed by duplicatures of the lining membrane of the heart, strengthened by intervening

layers of fibrous tissue: their central parts are comparatively thick and strong, their marginal portions thin and translucent, and in the angles between the latter small intermediate segments are sometimes seen. Their bases are attached to a fibrous ring surrounding the atrioventricular orifice and are also joined to each other so as to form a continuous annular membrane, while their apices project into the ventricular cavity. Their atrial surfaces, directed towards the blood-current from the atrium, are smooth; their ventricular surfaces, directed towards the wall of the ventricle, are rough and irregular and, together with the apices and margins of the cusps, give attachment to a number of delicate tendinous cords, the *chordæ tendineæ*.

The *trabeculæ carneæ* are rounded or irregular muscular columns which project from the whole of the inner surface of the ventricle, with the exception of the conus arteriosus. They are of three kinds: some are ridges, others are fixed at their extremities but free in the middle, while a third set (*musculi papillares*) are continuous by their bases with the wall of the ventricle, while their apices project into the cavity, and give origin to the *chordæ tendineæ* which pass to be attached to the segments of the tricuspid valve. There are two papillary muscles, anterior and posterior: of these, the anterior is the larger, and its *chordæ tendineæ* are connected with the anterior and posterior cusps of the valve; the posterior sometimes consists of two or three parts, and its *chordæ tendineæ* are connected with the posterior and medial cusps. Some *chordæ tendineæ* also spring directly from the ventricular septum, or from small papillary eminences on it, and pass to the anterior and medial cusps. A muscular band, well marked in sheep and some other animals, frequently extends from the base of the anterior papillary muscle to the ventricular septum. From its attachments it may assist in preventing over-distension of the ventricle, and so has been named the *moderator band*.

The *pulmonary semilunar valves* (figs. 602, 603) are three in number, two in front and one behind, formed by duplicatures of the lining membrane, strengthened by fibrous tissue. They are attached, by their convex margins, to the wall of the pulmonary artery at its junction with the ventricle, their free borders being directed upwards into the lumen of the vessel. The free and attached margins of each are strengthened by tendinous fibres, and the former presents, at its middle, a thickened nodule (*corpus Arantii*). From this nodule tendinous fibres radiate through the segment to its attached margin, but are absent from two narrow crescentic portions, the *lunula*, placed one on either side of the nodule immediately adjoining the free margin (fig. 606). Between the semilunar valves and the wall of the pulmonary artery are three pouches or sinuses (*sinuses of Valsalva*).

The *left atrium* is rather smaller than the right, but its walls are thicker, measuring about 3 mm.; it consists, like the right, of two parts, a *principal cavity* and an *auricula*.

The *principal cavity* is cuboidal in form, and concealed, in front, by the pulmonary artery and aorta; in front and to the right, it is separated from the right atrium by the atrial septum; opening into it on either side are the two pulmonary veins.

The *auricula* is somewhat constricted at its junction with the principal cavity; it is longer, narrower, and more curved than that of the right atrium,

FIG. 604.—The bases of the ventricles, exposed by removal of the atria.

and its margins are more deeply indented. It is directed forwards and towards the right, and overlaps the root of the pulmonary artery.

The interior of the left atrium (fig. 605) presents the following parts for examination :

Orifices of the four pulmonary veins.
Left atrioventricular orifice.
Foramina venarum minimarum.
Musculi pectinati.

The *pulmonary veins*, four in number, open into the upper part of the posterior surface of the left atrium—two on either side of its middle line : they are not provided with valves. The two left veins frequently end by a common opening.

FIG. 605.—Interior of left side of heart.

The *left atrioventricular orifice* is the aperture between the left atrium and ventricle ; it is smaller than the right atrioventricular orifice.

The *foramina venarum minimarum* are the orifices of minute veins (*venæ cordis minimæ*) which return blood directly from the muscular substance of the heart.

The *musculi pectinati*, fewer and smaller than those in the right atrium, are confined to the inner surface of the auricle.

On the atrial septum may be seen a lunate impression, bounded below by a crescentic ridge, the concavity of which is turned upwards. The depression is just above the fossa ovalis of the right atrium.

The *left ventricle* is longer and more conical in shape than the right, and on transverse section its cavity presents an oval or nearly circular outline. It forms a small part of the sternocostal, and a considerable part of the diaphragmatic, surface of the heart ; it also forms the apex of the heart. Its walls are about three times as thick as those of the right ventricle.

Its interior (fig. 605) presents the following parts for examination :

Orifices { Left atrioventricular.
Aortic.
Trabeculæ carneæ.

Valves { Bicuspid or mitral.
Aortic.
Chordæ tendineæ.

The *left atrioventricular orifice* is placed below and to the left of the *aortic orifice*. It is a little smaller than the right atrioventricular orifice, admitting only three fingers. It is surrounded by a dense fibrous ring and is guarded by the bicuspid or mitral valve.

The *aortic orifice* is a circular aperture in front and to the right of the atrioventricular orifice, from which it is separated by the anterior cusp of the bicuspid valve. Its orifice is guarded by the *aortic semilunar valves*. The portion of the ventricle immediately below the aortic orifice is termed the *aortic vestibule*, and possesses fibrous instead of muscular walls.

The *bicuspid* or *mitral valve* (figs. 604, 605) is attached to the circumference of the left atrioventricular orifice in the same way that the tricuspid valve is on the right side. It consists of two triangular cusps, formed by duplicatures of the lining membrane, strengthened by fibrous tissue, and containing a few muscular fibres. The cusps are of unequal size, and are larger, thicker, and stronger than those of the tricuspid valve. The larger cusp is placed in front and to the right between the atrioventricular and aortic orifices, and is known as the *anterior* or *aortic cusp*; the smaller or *posterior cusp* is placed behind and

FIG. 606.-Aorta laid open to show the semilunar valves.

to the left of the opening. Two smaller cusps are usually found at the angles of junction of the larger. The cusps of the bicuspid valve are furnished with chordæ tendineæ, which are attached in a manner similar to those on the right side of the heart; they are, however, thicker, stronger, and less numerous.

The *aortic semilunar valves* (figs. 604, 606) are three in number, and surround the orifice of the aorta; two are posterior (right and left) and one is anterior. They are similar in structure, and in their mode of attachment, to the pulmonary semilunar valves, but are larger, thicker, and stronger; the lunulæ are more distinct, and the noduli or corpora Arantii thicker and more prominent. Opposite the valves the aorta presents slight dilatations, the *aortic sinuses* (sinuses of Valsalva) which are larger than those at the origin of the pulmonary artery.

The *trabeculæ carneæ* are of three kinds, like those in the right ventricle, but they are more numerous, and present a dense interlacement, especially at the apex, and upon the posterior wall, of the ventricle. The *musculi papillares* are two in number, one springing from the anterior, the other from the posterior wall; they are of large size, and end in rounded extremities from which the chordæ tendineæ arise. The chordæ tendineæ from each papillary muscle are connected to both cusps of the bicuspid valve.

The *ventricular septum* (fig. 607) is directed obliquely backwards and to the right, and is curved with the convexity towards the right ventricle; its margins correspond with the anterior and posterior longitudinal sulci on the surface of the heart. The greater portion of the septum is thick and muscular.

and constitutes the *muscular ventricular septum*; but its upper and posterior part, which separates the aortic vestibule from the lower part of the right atrium and upper part of the right ventricle, is thin and fibrous, and is termed the *membranous ventricular septum*. An abnormal communication may exist between the ventricles at this part, owing to defective development of the membranous septum.

Structure.—The heart consists of muscular fibres (*myocardium*), and of fibrous rings which serve for their attachment. It is covered by the visceral layer of the serous pericardium (*epicardium*), and lined by the *endocardium*.

The *endocardium* is a thin, smooth, glistening membrane which lines the inner surface of the heart; it assists in forming the valves by its reduplications, and is

FIG. 607.—Section of the heart showing the ventricular septum.

continuous with the lining membrane of the large blood-vessels. It consists of a layer of endothelial cells placed on a stratum of connective tissue and elastic fibres.

The *fibrous rings* surround the atrioventricular and arterial orifices, and are stronger on the left than on the right side of the heart. The atrioventricular rings serve for the attachment of the muscular fibres of the atria and ventricles, and for the attachment of the bicuspid and tricuspid valves. The left atrioventricular ring is closely connected, by its right margin, with the aortic arterial ring; between these and the right atrioventricular ring is a triangular mass of fibrous tissue, the *trigonum fibrosum*, which represents the *os cordis* of some of the larger animals, as the ox and elephant. There is also the tendon of the conus arteriosus, already referred to (p. 558).

The fibrous rings surrounding the arterial orifices serve for the attachment of the great vessels and semilunar valves. Each ring receives, by its ventricular margin, the attachment of some of the muscular fibres of the ventricles; its opposite margin presents three deep semicircular notches, to which the middle coat of the artery is firmly fixed. The attachment of an artery to its fibrous ring is strengthened by the external coat and epicardium externally, and by the endocardium internally. From the margins of the semicircular notches, the fibrous structure of the ring

is continued into the segments of the valves. The middle coat of the artery in this situation is thin, and the vessel is dilated to form the sinuses of the aorta and pulmonary artery.

The *muscular structure of the heart* consists of fibres, which are transversely and longitudinally striated (page 33), and present an exceedingly intricate interlacement. They comprise (a) the fibres of the atria, (b) the fibres of the ventricles, and (c) the atrioventricular bundle.

The *fibres of the atria* are arranged in two layers—a superficial, common to both atria, and a deep, proper to each. The *superficial fibres* are most distinct on the front of the atria, across the bases of which they run in a transverse direction, forming a thin and incomplete layer; some of them pass into the atrial septum. The *deep fibres* consist of looped and annular fibres. The *looped fibres* pass upwards over each atrium, and are attached by their extremities to the corresponding atrioventricular ring, in front and behind; the *annular fibres* surround the auriculæ, and form annular bands around the terminations of the veins and around the fossa ovalis.

The *fibres of the ventricles* are arranged in a complex manner, and various accounts have been given of their course and connexions; the following description is based

FIG. 608.—Apex of the heart to show the two vortices. (Mall.)

on that given by John Bruce MacCallum.* They consist of superficial and deep layers, all of which, with the exception of two, are inserted into the papillary muscles of the ventricles. The *superficial layers* comprise the following: (a) Fibres which spring from the tendon of the conus arteriosus (p. 558) and sweep downwards and towards the left across the anterior longitudinal sulcus and around the apex of the heart, where they form a vortex (fig. 608) and pass upwards and inwards to terminate in the papillary muscles of the left ventricle; those arising from the upper half of the tendon of the conus arteriosus pass to the anterior papillary muscle, those from the lower half to the posterior papillary muscle and the papillary muscles of the septum (fig. 609). (b) Fibres which arise from the right atrioventricular ring and run diagonally across the diaphragmatic surface of the right ventricle and round its right border on to its sternocostal surface, where they dip beneath the fibres just described, and, crossing the anterior longitudinal sulcus, wind around the apex of the heart and end in the posterior papillary muscle of the left ventricle. (c) Fibres which spring from the left atrioventricular ring, and, crossing the posterior longitudinal sulcus, pass successively into the right ventricle and end in its papillary muscles. The *deep layers* are three in number; they arise in the papillary muscles of one ventricle and, curving in an S shaped manner, turn in at the longitudinal sulcus and end in the papillary muscles of the other ventricle (fig. 610). The layer which is most superficial in the right ventricle lies next the lumen of the left, and vice versa. Those of the first layer almost encircle the right ventricle, and, crossing in the septum to the left, unite with

* *Johns Hopkins Hospital Reports*, vol. ix.

the superficial fibres from the right atrioventricular ring to form the posterior papillary muscle. Those of the second layer have a less extensive course in the wall of the right ventricle, and a correspondingly greater course in the left, where they join with the superficial fibres from the anterior half of the tendon of the conus arteriosus

FIG. 609.—Diagram of the superficial muscular fibres of the ventricles of the heart originating in the tendon of the conus arteriosus. (After MacCallum.)

to form the papillary muscles of the septum. Those of the third layer pass almost entirely round the left ventricle and unite with the superficial fibres from the lower half of the tendon of the conus arteriosus to form the anterior papillary muscle. Besides the layers just described there are two bands which do not end in papillary muscles. One springs from the right atrioventricular ring, crosses in the atrioventricular septum, encircles the deep layers of the left ventricle, and ends in the left atrioventricular ring. The second band is apparently confined to the left ventricle; it is attached to the left atrioventricular ring, and encircles the portion of the ventricle adjacent to the aortic orifice.

The *atrioventricular bundle* is a direct muscular connexion between the atria and the

ventricles. It arises in connexion with two small collections of spindle-shaped cells, the sino-atrial and atrioventricular nodes. The *sino-atrial node* is situated on the anterior border of the opening of the superior vena cava; from it strands of fusiform fibres run under the endocardium of the wall of the atrium to the atrioventricular node. The *atrioventricular node* lies near the orifice of the coronary sinus in the annular and septal fibres of the right atrium; from it the atrioventricular bundle passes forwards below the membranous septum, and divides into right and left fasciculi. These run down in the right and left ventricles, one on either side of the ventricular septum, covered by endocardium. In the lower parts of the ventricles they break up into numerous strands which end in an intricate network in the papillary muscles and ventricular muscle generally. The bundle, and its divisions are enveloped in a sheath of connective tissue; by injecting this sheath with Indian ink the ramifications of the bundle can be demonstrated. The greater portion of the atrioventricular bundle consists of narrow, somewhat fusiform fibres, but its terminal strands are composed of Purkinje fibres.

FIG. 610.—Diagram of the course of the deepest layer of the left ventricle. (After MacCallum.)

Kent has described a second atrioventricular bundle in the right lateral aspect of the heart, containing cardiac muscle-fibres, fine nerve-fibres, and fibres resembling those of Purkinje. This bundle is connected with a node in the wall of the right atrium, formed of fine, faintly striated muscle-fibres.

A. Morison * has shown that in the sheep and pig the atrioventricular bundle 'is a great avenue for the transmission of nerves from the auricular to the ventricular heart'; large and numerous nerve-trunks enter the bundle and course with it. Branches arise from these nerve-trunks and form plexuses around groups of Purkinje cells, and from these plexuses fine fibrils go to innervate individual cells.

Applied Anatomy.—Clinical and experimental evidence go to prove that this bundle conveys the impulse to systolic contraction from the atrial septum to the ventricles, and much attention has recently been paid to it, because it appears to become fibrosed and to lose much of its conducting power (heart-block) in many cases of Adams-Stokes' syndrome. This condition is characterised by a slow pulse, a tendency to syncopal or epileptiform seizures, and the fact that while the cardiac atria beat at a normal rate, the ventricles contract much less frequently.

Vessels and Nerves.—The *arteries* supplying the heart are the right and left coronary branches of the aorta; the majority of the *veins* drain into the right atrium, but the left atrium receives a few minute veins from the adjacent part of the heart.

The *lymphatics* end in the thoracic and right lymphatic ducts.

The *nerves* are derived from the cardiac plexus, which is formed by branches from the vagi and sympathetic. They are freely distributed both on the surface and in the substance of the heart, the separate nerve-filaments being furnished with small ganglia. The atrioventricular bundle receives nerve-fibres from ganglia in the atrial septum. Other ganglia are found in relation with the sino-atrial node, and supply it with nerve-filaments.

The cardiac cycle and the actions of the valves.—By the contractions of the heart the blood is pumped through the arteries to all parts of the body. These contractions occur regularly and at the rate of about seventy per minute. Each wave of contraction or *period of activity* is followed by a *period of rest*, the two periods constituting what is known as a *cardiac cycle*.

Each cardiac cycle consists of three phases, which succeed each other as follows: (1) a short simultaneous contraction of both atria, termed the *atrial systole*, followed, after a slight pause, by (2) a simultaneous, but more prolonged, contraction of both ventricles, named the *ventricular systole*, and (3) a *period of rest*, during which the whole heart is relaxed. The atrial contraction commences around the venous openings, and sweeping over the atria forces their contents through the atrio-ventricular openings into the ventricles, regurgitation into the veins being prevented by the contraction of their muscular coats. When the ventricles contract, the tricuspid and bicuspid valves are closed, and prevent the passage of the blood back into the atria; the *musculi papillares* at the same time are shortened, and, pulling on the chordæ tendinæ, prevent the inversion of the valves into the atria. As soon as the pressure in the ventricles exceeds that in the pulmonary artery and aorta, the valves guarding the orifices of these vessels are opened, and the blood is driven from the right ventricle into the pulmonary artery, and from the left into the aorta. The moment the systole of the ventricles ceases, the pressure of the blood in the pulmonary artery and aorta closes the pulmonary and aortic semilunar valves, thus preventing regurgitation of blood into the ventricles, and the valves remain shut until re-opened by the next ventricular systole. During the period of rest the tension of the tricuspid and bicuspid valves is relaxed, and blood flows from the veins through the atria into the ventricles. The filling of the ventricles is completed by the systole of the atria. The average duration of a cardiac cycle is about $\frac{8}{10}$ of a second, made up as follows:

Atrial systole, $\frac{1}{10}$.	Atrial diastole, $\frac{7}{10}$.
Ventricular systole, $\frac{3}{10}$.	Ventricular diastole, $\frac{5}{10}$.
Total systole, $\frac{4}{10}$.	Complete diastole, $\frac{4}{10}$.

The rhythmical action of the heart is *muscular* in origin—that is to say, the heart-muscle itself possesses the inherent property of contraction apart from any nervous stimulation. The more embryonic the muscle the better is it able to initiate the contraction wave; this explains why the normal systole of the heart starts at the entrance of the veins, for there the muscle is most embryonic in nature. A slight pause occurs between systole of the atria and that of the ventricles. This

* *Journal of Anatomy and Physiology*, vol. xlvii.

is due to the fact that the contraction of the ventricles is excited by an impulse conveyed by the atrioventricular bundle, conduction along the fibres of which is relatively slow. The nerves, although not concerned in originating the contractions of the heart-muscle, play an important rôle in regulating their force and frequency in order to subserve the physiological needs of the organism.

Applied Anatomy.—Wounds of the heart are often immediately fatal, but not necessarily so. They may be non-penetrating, when death may occur from hæmorrhage if one of the coronary vessels has been wounded, or subsequently from pericarditis. Even a penetrating wound is not necessarily fatal, as many cases have been recorded in which the wound has been sutured successfully.

CHIEF PECULIARITIES IN THE VASCULAR SYSTEM OF THE FŒTUS

The development of the heart and vascular system is described on pages 109 to 128.

The chief peculiarities of the foetal heart are the direct communication between the atria through the foramen ovale, and the large size of the valve of the inferior vena cava. Amongst other peculiarities the following may be noted: (1) In early foetal life the heart lies immediately below the mandibular arch, and as development proceeds it is gradually drawn within the thorax. (2) For a time the atrial portion exceeds the ventricular in size, and the walls of the ventricles are of equal thickness; towards the end of foetal life the ventricular portion becomes the larger, and the wall of the left ventricle exceeds that of the right in thickness. (3) Its size is large as compared with that of the rest of the body, the proportion at the second month being 1 to 50, and at birth 1 to 120, while in the adult the average is about 1 to 160.

The *foramen ovale* forms a free communication between the atria until the end of foetal life: it is obliterated shortly after birth (pages 115, 116).

The *valve of the inferior vena cava* directs the blood from that vessel through the foramen ovale into the left atrium.

The chief peculiarities in the arterial system of the foetus are the communication between the pulmonary artery and the aorta by means of the ductus arteriosus, and the continuation of the hypogastric arteries as the umbilical arteries to the placenta.

The *ductus arteriosus* is a short tube, about 1.25 cm. in length at birth, and of the diameter of a goose-quill. In early foetal life it forms the continuation of the pulmonary artery, and opens into the aorta, just beyond the origin of the left subclavian artery; and so conducts the greater amount of the blood from the right ventricle into the aorta. When the branches of the pulmonary artery have become larger relatively to the ductus arteriosus, the latter is chiefly connected to the left pulmonary artery. It is obliterated within a few days after birth.

In the foetus the *hypogastric arteries* are continued along the sides of the urinary bladder, thence upwards on the back of the anterior abdominal wall to the umbilicus; here they pass out of the abdomen and run, under the name of the *umbilical arteries*, in the umbilical cord to the placenta. They convey blood from the foetus to the placenta.

The chief peculiarities in the venous system of the foetus are the communications established between the placenta and the liver and portal vein, through the umbilical vein; and between the umbilical vein and the inferior vena cava through the ductus venosus.

THE FŒTAL CIRCULATION (fig. 611)

The foetal blood is carried to the placenta by the hypogastric and umbilical arteries, and returned from the placenta to the foetus by the two umbilical veins. These veins unite in the umbilical cord to form a single vein (*vena umbilicalis impar*) which divides within the embryo into a right and a left umbilical vein. After the formation of the liver the right umbilical vein atrophies and disappears, but the left persists until the end of foetal life. It enters the abdomen at the umbilicus, and passes along the free margin of the falciform

ligament of the liver, to the under surface of that organ, where it gives off two or three branches, one of large size to the left lobe, and others to the lobus quadratus and lobus caudatus. At the porta hepatis or transverse fissure

FIG. 611.—Plan of the foetal circulation.

In this plan the arrows represent the course which the blood takes in the heart and vessels.

of the liver it divides into two branches : of these, the larger is joined by the portal vein, and enters the right lobe ; the smaller is continued upwards, under the name of the ductus venosus, and joins the inferior vena cava. The blood conveyed by the left umbilical vein passes to the inferior vena cava in three different ways. Some enters the liver directly and is carried to the inferior vena cava by the hepatic veins ; a considerable quantity circulates

through the liver with the portal venous blood, before entering the inferior vena cava by the hepatic veins; the remainder passes directly into the inferior vena cava through the ductus venosus.

In the inferior vena cava, the blood carried by the ductus venosus and hepatic veins mixes with that returning from the lower extremities and abdominal wall. It enters the right atrium, and, guided by the valve of the inferior vena cava, passes through the foramen ovale into the left atrium, where it mingles with a small quantity of blood returned from the lungs by the pulmonary veins. From the left atrium it passes into the left ventricle, and from that cavity into the aorta, by means of which it is distributed almost entirely to the head and upper extremities, a small quantity being probably carried into the descending aorta. The blood from the head and upper extremities is returned by the superior vena cava to the right atrium, where it mixes with a small portion of that returned by the inferior vena cava. From the right atrium the blood passes into the right ventricle, and thence into the pulmonary artery. The lungs of the foetus being inactive, only a small quantity of the blood conveyed by the pulmonary artery is distributed to them by the right and left pulmonary arteries, and returned by the pulmonary veins to the left atrium: the greater part passes through the ductus arteriosus into the aorta, where it mixes with the small quantity of blood transmitted by the left ventricle into this part of the aorta. It descends through the aorta and is in part distributed to the lower extremities and the viscera of the abdomen and pelvis, but most of it is conveyed by the umbilical arteries to the placenta.

From the preceding account of the circulation of the blood in the foetus the following facts will be evident: 1. The placenta serves the purposes of nutrition and excretion, receiving the impure blood from the foetus, and returning it purified and charged with additional nutritive material. 2. A large part of the blood of the left umbilical vein traverses the liver before entering the inferior vena cava; this is correlated with the large size of the liver, especially at an early period of foetal life. 3. The right atrium is the point of meeting of a double current, the blood from the inferior vena cava being guided by the valve of this vessel through the foramen ovale into the left atrium, while that in the superior vena cava descends into the right ventricle. At an early period of foetal life it is highly probable that the two streams are quite distinct, for the inferior vena cava opens almost directly into the left atrium, and the valve of the inferior vena cava would exclude the current from the right ventricle. At a later period, as the separation between the two atria becomes more distinct, it seems probable that some mixture of the two streams must take place. 4. The pure blood carried from the placenta to the foetus, mixed with the blood from the portal vein and inferior vena cava, passes almost directly to the arch of the aorta, and is distributed by the branches of that vessel to the head and upper extremities. 5. The blood contained in the descending aorta, chiefly derived from that which has already circulated through the head and limbs, together with a small quantity from the left ventricle, is distributed to the abdomen and lower extremities.

CHANGES IN THE VASCULAR SYSTEM AT BIRTH

At birth, when respiration is established, an increased amount of blood from the pulmonary artery passes through the lungs, and the placental circulation is cut off. The foramen ovale is closed by the septum secundum (p. 115) about the tenth day after birth; sometimes a slit-like opening is left between the two atria.

The *ductus arteriosus* begins to contract immediately after respiration is established, and is completely closed between the fourth and tenth days; it ultimately forms an impervious cord, the *ligamentum arteriosum*, which connects the left pulmonary artery to the arch of the aorta.

Of the *hypogastric arteries*, the parts extending from the sides of the bladder to the umbilicus become obliterated between the second and fifth days after birth, and project as fibrous cords, termed the lateral umbilical ligaments, towards the abdominal cavity, carrying on them folds of peritoneum.

The *left umbilical vein* and the *ductus venosus* are completely obliterated between the second and fifth days after birth; the former becomes the ligamentum teres, the latter the ligamentum venosum, of the liver.

THE ARTERIES

The distribution of the systemic arteries is like a highly branched tree, the common trunk of which, formed by the aorta, commences at the left ventricle, while the smallest ramifications extend to the peripheral parts of the body and the contained organs. Arteries are found in all parts of the body, except in the hairs, nails, epidermis, cartilages, and cornea; the larger trunks usually occupy the most protected situations, running, in the limbs, along the flexor surfaces, where they are less exposed to injury.

There is considerable variation in the mode of division of the arteries: occasionally a short trunk subdivides into several branches at the same point, as in the coeliac artery and the thyrocervical trunk; usually the vessel gives off several branches in succession, and still continues as the main trunk, as in the arteries of the limbs.

A branch of an artery is smaller than the trunk from which it arises; but if an artery divides into two branches, the combined sectional area of the two vessels is, in nearly every instance, somewhat greater than that of the trunk; and the combined sectional area of all the arterial branches greatly exceeds that of the aorta.

The arteries unite with one another, forming what are called *anastomoses*. Anastomosis between trunks of nearly equal size is found in the brain, where the two vertebral arteries unite to form the basilar, and the two anterior cerebral arteries are connected by the anterior communicating artery; and in the abdomen, where the intestinal arteries have very ample anastomoses between their larger branches. In the limbs, the anastomoses are largest and most numerous around the joints; the branches arising from an artery above the joint uniting with branches from the vessels below. These anastomoses are of considerable interest to the surgeon, as it is by their enlargement that a *collateral circulation* is established after the application of a ligature to a main artery. The smaller branches of arteries anastomose more frequently than the larger; and between the smallest twigs these anastomoses are so numerous that they constitute a close network pervading nearly every tissue of the body.

Applied Anatomy.—The walls of all the arteries, and most of all of the aorta, are liable to various forms of hardening known collectively as *arteriosclerosis*, with loss of elasticity, that are of the greatest clinical importance. The two chief varieties of arteriosclerosis are: (1) hypertrophy of the muscular tunica media of the arteries, clinically associated with chronic arterial vasoconstriction and high blood-pressure, and (2) atheroma or atherosclerosis, essentially a senile degenerative change of the intima, that leads to loss of arterial elasticity by the replacement of elastic by fibrous tissue. Whatever the cause of arterial sclerosis its chief ill-effects on the patient are two. In the first place, it is associated with a permanent and often considerable rise in the arterial blood-pressure, entailing a corresponding hypertrophy of the heart: in the second, it weakens the vessel walls, rendering them more liable to rupture, while at the same time it is apt to lessen the calibre of the affected vessels.

The arteries are also frequently attacked by syphilis, which gives rise to inflammation and degeneration of their middle coats. Recent researches* go to prove that arterial aneurysms, other than those due to direct injury, occur almost solely in syphilitic patients.

PULMONARY ARTERY

The **pulmonary artery** (figs. 612, 613) conveys venous blood from the right ventricle of the heart to the lungs. It is about 5 cm. in length and 3 cm. in diameter, and arises from the *conus arteriosus of the right ventricle*. It runs upwards and backwards, passing at first in front and then to the left of the ascending aorta, as far as the under surface of the aortic arch, where it divides, about the level of the fibrocartilage between the fifth and sixth thoracic vertebræ, into right and left branches of nearly equal size.

* C. U. Aitchison, *Arch. of the Pathological Institute of the London Hospital*, 1908, ii. p. 1.

Relations.—The whole of this vessel is contained within the pericardium. It is enclosed in a tube of the visceral layer of the serous pericardium, common to it and the ascending aorta. The fibrous layer of the pericardium is gradually lost upon the external coats of the two branches of the artery. In front, the pulmonary artery is separated from the anterior end of the second left intercostal space by the pleura, the left lung, and the pericardium; it rests at first upon the ascending aorta; higher up it lies in front of the left atrium, and the ascending aorta is on its right side. On either side of its origin is the auricle of the corresponding atrium, and a coronary artery; the left coronary artery, in the first part of its course passes behind the vessel. The superficial part of the cardiac plexus lies above its bifurcation, between it and the arch of the aorta.

The right branch of the pulmonary artery, longer and larger than the left, runs horizontally to the right, behind the ascending aorta, superior vena cava,

FIG. 612.—Diagram of a transverse section of thorax, showing relations of pulmonary artery, etc.

and upper right pulmonary vein, and in front of the right bronchus, to the root of the right lung, where it divides into two branches. The lower and larger of these is distributed to the middle and lower lobes of the lung; the upper and smaller accompanies the eparterial bronchus to the upper lobe.

The left branch of the pulmonary artery, a little shorter and smaller than the right, runs horizontally in front of the descending aorta and left bronchus to the root of the left lung, where it divides into two branches, one for either lobe of the lung. Above, it is united to the concavity of the aortic arch by the ligamentum arteriosum, on the left of which is the left recurrent nerve, and on the right the superficial part of the cardiac plexus. Below, it is joined to the upper left pulmonary vein by the ligament of the left vena cava (p. 552).

The terminal branches of the pulmonary arteries are described with the anatomy of the lungs.

Applied Anatomy.—Stenosis (narrowing) or atresia (non-perforation) of the pulmonary orifice, usually combined with other developmental anomalies such as defect of the upper part of the interventricular septum, patency of the ductus arteriosus, or patency of the

foramen ovale, is the commonest form of congenital heart disease. It is due to maldevelopment, and not to fetal endocarditis; possibly, as Keith suggests, to malformation of the bulbus cordis. In well-marked cases the child with congenital heart disease is cyanosed, short of breath on exertion, and puny, generally dying of sudden heart failure or bronchitis before adolescence. The chief signs of the condition are the loud, harsh systolic cardiac murmur best heard over the second left costal cartilage, cyanosis, clubbing of the finger-tips, and the presence of an excess of red corpuscles in the blood.

Embolism of the pulmonary artery by a clot of blood coming from the right side of the heart in patients with heart-disease, or from a thrombosed vein in cases, for example, of influenza, enteric fever, puerperal sepsis, or fractured limbs, is a common cause of sudden or rapid death. The patient may cry out with sudden excruciating pain in the precordia when the detached embolus lodges, and after a brief period of intense dyspnoea, pallor, and anguish, die.

THE AORTA

The **aorta** is the main trunk of a series of vessels which convey the oxygenated blood to the tissues of the body. It begins at the upper part of the left ventricle, where it is about 3 cm. in diameter, and after ascending for a short distance, arches backwards and to the left, over the root of the left lung; it then descends within the thorax on the left side of the vertebral column, passes into the abdominal cavity through the aortic hiatus in the Diaphragm, and ends, considerably diminished in size (about 1.75 cm. in diameter), opposite the left half of the lower border of the fourth lumbar vertebra, by dividing into the right and left common iliac arteries. Hence it is described in several portions, viz. the *ascending aorta*, the *arch of the aorta*, and the *descending aorta*, which last is divided into the *thoracic* and *abdominal aortae*.

ASCENDING AORTA

The **ascending aorta** (fig. 613) is about 5 cm. long. It begins at the upper part of the base of the left ventricle, on a level with the lower border of the third costal cartilage, behind the left half of the sternum; it passes obliquely upwards, forwards, and to the right, in the direction of the heart's axis, as high as the upper border of the second right costal cartilage, describing a slight curve in its course, and being situated behind the posterior surface of the sternum. At its origin it presents, opposite the segments of the aortic valve, three small dilatations called the aortic sinuses. At the union of the ascending aorta with the aortic arch the calibre of the vessel is slightly increased, owing to a bulging of its right wall. This dilatation is termed the *bulb of the aorta*, and on transverse section presents a somewhat oval figure.

Relations.—The ascending aorta is contained within the pericardium, and is enclosed in a tube of the serous pericardium, common to it and the pulmonary artery. It is covered at its commencement by the trunk of the pulmonary artery and the right auricle, and, higher up, is separated from the sternum by the pericardium, the right pleura, the anterior margin of the right lung, some loose areolar tissue, and the remains of the thymus; posterior to it are the left atrium, the right pulmonary artery, and the right bronchus. On its *right side* are the superior vena cava and right atrium, the former lying partly behind it; on its *left side* is the pulmonary artery.

Branches.—The branches of the ascending aorta are the right and left coronary arteries (figs. 601, 613) which supply the heart; they arise from the aortic sinuses immediately above the attached margins of the aortic semilunar valves.

✓ The **right coronary artery** arises from the anterior aortic sinus. It passes at first between the conus arteriosus and the right auricle and then runs in the right portion of the coronary sulcus, coursing on the front of the heart from left to right, and then on the diaphragmatic surface of the heart from right to left as far as the posterior longitudinal sulcus, down which it is continued to the apex of the heart as the *posterior descending branch*. It gives off a large *marginal branch* which follows the acute margin of the heart and ramifies on both surfaces of the right ventricle. It also supplies branches to the right atrium and to the part of the left ventricle which adjoins the posterior longitudinal sulcus.

✓ The **left coronary artery**, larger than the right, arises from the left posterior aortic sinus and divides into an anterior descending and a circumflex branch.

anterior descending branch passes at first behind the pulmonary artery and then comes forward between that vessel and the left auricle to reach the anterior longitudinal sulcus, along which it descends to the incisura apicis cordis; it gives branches to both ventricles. The *circumflex branch* follows the left part of the coronary sulcus, running first to the left and then to the right, reaching nearly as far as the posterior longitudinal sulcus; it gives branches to the left atrium and ventricle.

FIG. 613.—The arch of the aorta, and its branches

FIG. 614.—Plan of the branches.

There is a free anastomosis between the minute branches of the two coronary arteries in the substance of the heart.

Peculiarities.—The coronary arteries occasionally arise by a common trunk; their number may be increased to three or four.

Applied Anatomy.—The sudden blocking of a coronary artery by an embolus, or its more gradual obstruction by arterial disease or thrombosis, is a common cause of sudden death in persons past middle age. If the obstruction to the passage of blood is incomplete, true *angina pectoris* may occur. In this condition the patient is suddenly seized with a spasm of agonising pain in the precordial region and down the left arm, together with an indescribable sense of anguish. He may die in such an attack, or succumb a few hours or days later from heart failure, or survive a number of attacks.

ARCH OF THE AORTA

The **arch of the aorta** (fig. 613) connects the ascending with the descending aorta; it begins at the level of the upper border of the second right sternocostal articulation, and runs at first upwards, backwards, and to the left in front of the trachea; it is then directed backwards on the left side of the trachea, and finally passes downwards on the left side of the body of the fourth thoracic vertebra, at the lower border of which it is continuous with the descending aorta. It thus forms two curvatures: one with its convexity upwards, the other with its convexity forwards and to the left. Its upper border is usually about 2.5 cm. below the superior border of the manubrium sterni.

Relations.—The arch of the aorta is covered *anteriorly* by the pleuræ and anterior margins of the lungs, and by the remains of the thymus. As the vessel runs backwards its *left* side is in contact with the left lung and pleura. Passing downwards on the left side of this part of the arch are four nerves; in order from before backwards these are: the left phrenic, the lower of the superior cardiac branches of the left vagus, the superior cardiac branch of the left sympathetic, and the trunk of the left vagus. As the last nerve crosses the arch it gives off its recurrent branch which hooks round below the vessel and then passes upwards on its right side. The left superior intercostal vein runs obliquely upwards and forwards on the left side of the arch, between the phrenic and vagus nerves. On the *right* are the deep part of the cardiac plexus, the left recurrent nerve, the œsophagus, and the thoracic duct; the trachea lies behind and to the right of the vessel. *Above* are the innominate, left common carotid, and left subclavian arteries, which arise from the convexity of the arch and are crossed close to their origins by the left innominate vein. *Below* are the bifurcation of the pulmonary artery, the left bronchus, the ligamentum arteriosum, the superior part of the cardiac plexus, and the left recurrent nerve. As already stated, the ligamentum arteriosum connects the commencement of the left pulmonary artery to the aortic arch.

In the foetus the lumen of the aorta is considerably narrowed between the origin of the left subclavian artery and the attachment of the ligamentum arteriosum, forming what is termed the *aortic isthmus*, while immediately beyond the ductus arteriosus the vessel presents a fusiform dilatation which is termed the *aortic spindle*—the point of junction of the two parts being marked in the concavity of the arch by an indentation or angle. These conditions persist, to some extent, in the adult, where His found that the average diameter of the spindle exceeded that of the isthmus by 3 mm.

Peculiarities.—The summit of the arch of the aorta is usually about 2.5 cm. below the upper border of the sternum: but it may reach nearly to the top of the bone. Occasionally it is found 4 cm., more rarely from 5 to 8 cm., below this point. Sometimes the aorta arches over the root of the right lung (right aortic arch) instead of over that of the left, and passes down on the right side of the vertebral column, a condition which is found in birds. In such cases there is a transposition of the thoracic and of the abdominal viscera. Less frequently the aorta, after arching over the root of the right lung, is directed to its usual position on the left side of the vertebral column; this peculiarity is not accompanied by transposition of the viscera. The aorta occasionally divides, as in some quadrupeds, into an ascending and a descending trunk, the former of which is directed vertically upwards, and subdivides into three branches, to supply the head and upper extremities. Sometimes the aorta subdivides near its origin into two branches, which soon reunite; in one case of this kind the œsophagus and trachea passed through the interval between the two branches; this is the normal condition of the vessel in the reptilia.

Applied Anatomy.—Of all the vessels of the arterial system, the aorta, and more especially its arch, is most frequently the seat of disease; hence it is important to consider some of the consequences that may ensue from aneurysm of this part.

Aneurysm of the ascending aorta, in the situation of the aortic sinuses, in the great majority of cases, affects the anterior sinus; this is mainly owing to the fact that the regurgitation of blood upon the sinuses takes place chiefly on the anterior aspect of the vessel. As the aneurysmal sac enlarges, it may compress any or all of the structures in immediate proximity with it, but chiefly projects towards the right anterior side; and, consequently, interferes mainly with those structures that have a corresponding relation with the vessel. If it project forwards, it may destroy the sternum and the cartilages of the ribs, usually on the right side, and appear as a pulsating tumour on the front of the chest, just below the manubrium; or it may burst into the pericardium, or may compress, or open into the right lung, the trachea, bronchi, or œsophagus. In the majority

of cases it bursts into the cavity of the pericardium, the patient suddenly drops down dead, and upon a post-mortem examination, the pericardial sac is found full of blood; or it may compress the right atrium, or the pulmonary artery, and adjoining part of the right ventricle, and open into one or the other of these parts. It may press upon the superior vena cava or the innominate veins, causing great venous engorgement. The face becomes livid and swollen, the right arm and anterior thoracic wall oedematous, and the congestion of the brain gives rise to headache and vertigo. An aneurysm has occasionally perforated into the superior vena cava, setting up an arteriovenous aneurysm. When this happens the patient suddenly becomes very short of breath, intensely congested and oedematous in the face and upper part of the body, and develops a palpable thrill and a continuous humming murmur, loudest during systole, over the sternum. Death follows a few days or weeks after such a perforation; and somewhat similar symptoms are occasioned when an aortic aneurysm erodes and bursts into the pulmonary artery.

Regarding the arch of the aorta, the student is reminded that the vessel lies against the trachea, oesophagus, and thoracic duct; that the recurrent nerve winds around it; and that from its upper part are given off three large trunks, which supply the head, neck, and upper extremities. An aneurysmal tumour taking origin from the posterior part of the vessel, its most usual site, may press upon the trachea and give rise to the sign known as 'tracheal tugging,' impede the breathing, or produce cough, dyspnoea, bronchiectasis, hæmoptysis, or stridulous breathing, or it may ultimately burst into that tube, producing fatal hæmorrhage. Again, its pressure on the left recurrent nerve may give rise to symptoms of laryngeal paralysis; or it may press upon the thoracic duct and destroy life by inanition; or it may involve the oesophagus, producing dysphagia, and has not infrequently been mistaken for oesophageal stricture; or it may burst into the oesophagus, when fatal hæmorrhage will occur. Compression or stretching of the sympathetic filaments may, in the former case, produce dilatation of the pupil; in the latter, contraction, if the conducting power is abolished, on the affected side. This has proved to be an important diagnostic sign in this disease; it has also been attributed to lowering of the arterial pressure in the iris, which is dilated, the lowering being due to partial obstruction of the orifice of the innominate artery on the right side, or of the common carotid on the left, as the case may be, by aneurysmal deformation of the aortic arch at the point where these vessels arise. Again, the innominate artery, or the subclavian, or left carotid, may be so obstructed by clots as to produce a weakness, or even a disappearance, of the pulse in one or the other wrist, or in the left superficial temporal artery; or the tumour may present itself at or above the manubrium, generally either in the median line, or to the right of the sternum, and may simulate an aneurysm of one of the arteries of the neck.

Many of the physical signs of an aortic aneurysm may be simulated with extraordinary fidelity by the preternatural pulsation or throbbing of a distended and elastic aorta, when no true aneurysmal dilatation exists. This condition may be met with in young persons with aortic reflux and greatly hypertrophied hearts, in patients who are of a neurotic or hysterical temperament, and in cases of Graves's disease or of marked anæmia. The condition is known as dynamic dilatation of the aorta, and in no way threatens life.

Branches (figs. 613, 614).—Three branches are given off from the summit of the arch of the aorta, viz.: the innominate, the left common carotid, and the left subclavian.

Peculiarities.—The branches may spring from the commencement of the arch or upper part of the ascending aorta; or the distance between them at their origins may be increased or diminished, the most frequent change in this respect being the approximation of the left carotid to the innominate artery.

The number of the primary branches may be reduced to one; more commonly there are two, the left carotid arising from the innominate artery, or (more rarely) the carotid and subclavian arteries of the left side arising from a left innominate artery. But the number may be increased to four, through the right carotid and subclavian arteries arising directly from the aorta; in most of these cases the right subclavian arises from the left end of the arch; in other cases it is the second or third branch given off. Another common variation in which there are four primary branches is that where the left vertebral artery arises from the arch of the aorta between the left carotid and subclavian arteries. Lastly, the number of trunks may be increased to five or six; in these instances, the external and internal carotid arteries arise separately, the common carotid being absent on one or both sides. In some few cases six branches have been found, and this condition is associated with the origin of both vertebral arteries from the arch.

When the aorta arches over to the right side, the three branches have an arrangement the reverse of what is usual: there is a left innominate artery, and the right carotid and right subclavian arise separately. In other cases, where the aorta takes its usual course, the two carotids may be joined in a common trunk, and the subclavians arise separately from the arch, the right subclavian generally arising from the left end of the arch.

Other arteries may spring from the arch of the aorta. Of these the most common are the bronchial, one or both, and the thyroidea ima; the internal mammary and the inferior thyreoid have been seen to arise from it.

INNOMINATE ARTERY (fig. 613)

The innominate artery (*arteria anonyma*) is the largest branch of the arch of the aorta, and is from 4 to 5 cm. in length. It arises from the convexity of the arch of the aorta, posterior to the centre of the manubrium sterni; it passes obliquely upwards, backwards, and to the right to the level of the upper border of the right sternoclavicular articulation, where it divides into the right common carotid and right subclavian arteries.

Relations.—*Anteriorly*, it is separated from the manubrium sterni by the Sternohyoideus and Sternothyroideus, the remains of the thymus, the left innominate and right inferior thyroid veins which cross its root, and sometimes the superior cardiac branches of the right vagus nerve. *Posterior* to it is the trachea, which it crosses obliquely. On the *right side* are the right vagus nerve, the right innominate vein, the superior vena cava, the right phrenic nerve, and the pleura; and on the *left side*, the remains of the thymus, the origin of the left common carotid artery, the inferior thyroid veins, and the trachea.

Branches.—The innominate artery is usually devoid of branches, but occasionally a small one, the *thyroidea ima*, arises from it, and sometimes it gives off a *thymic* or a *bronchial branch*.

The *thyroidea ima* ascends in front of the trachea to the lower part of the thyroid gland, which it supplies. It varies greatly in size, and appears to compensate for deficiency or absence of one of the other thyroid vessels. It occasionally arises from the aorta, the right common carotid, the subclavian or the internal mammary.

Peculiarities.—The innominate artery sometimes divides above the level of the sternoclavicular joint, less frequently below it. When the aortic arch is on the right side, the innominate artery is directed to the left side of the neck.

Applied Anatomy.—Aneurysm of the innominate artery not infrequently occurs as an accompaniment to aneurysm of the arch of the aorta. It causes bulging of the right sternoclavicular articulation, pushing forwards the Sternocleidomastoideus muscle and filling up the jugular notch. It produces serious pressure symptoms: from pressure on the innominate veins it may cause oedema of the upper extremities, and of the head and neck; from pressure on the trachea it produces dyspnoea; and from pressure on the right recurrent nerve, hoarseness and laryngeal cough.

Although the operation of tying the innominate artery has been performed by several surgeons, few successes have been recorded. The chief danger of the operation appears to be the frequency of secondary hemorrhage; but in the present day, with the practice of aseptic surgery and our greater knowledge of the use of the ligature, more favourable results may be anticipated. The main obstacles to the operation are the deep situation of the artery behind the sternum and the number of important structures which surround it.

In order to apply a ligature to this vessel, the patient is to be placed upon his back with the thorax slightly raised, the head bent a little backwards, and the right shoulder strongly depressed, so as to draw out the artery from behind the sternum into the neck. An incision 7 cm. or more in length is then made along the anterior border of the Sternocleidomastoideus, terminating at the sternal end of the clavicle. From this point, a second incision is carried about the same length along the upper border of the clavicle. The skin is then dissected back, and the Platysma divided: the sternal end of the Sternocleidomastoideus is now brought into view, and a director being passed beneath it, and close to its deep surface so as to avoid any small vessels, it is to be divided: in like manner the clavicular origin is to be divided throughout the whole or greater part of its attachment. By pressing aside any loose cellular tissue or vessels that may now appear, the Sternohyoideus and Sternothyroideus muscles will be exposed, and must be divided. The inferior thyroid veins may come into view, and must be carefully drawn either upwards or downwards, by means of a blunt hook, or tied with double ligatures and divided. After tearing through a strong fibrocellular lamina, the right common carotid is brought into view, and being traced downwards, the innominate artery is reached. The left innominate vein should now be depressed; the right innominate vein, the internal jugular vein, and the vagus nerve drawn to the right side: and a curved aneurysm needle may then be passed around the vessel, close to its surface, and in a direction from below upwards and medially; care being taken to avoid the right pleural sac, the trachea, and cardiac nerves. The ligature should be applied to the artery as high as possible, in order to allow room between it and the aorta for the formation of the coagulum. The importance of avoiding the thyroid plexus of veins during the primary steps of the operation, and the pleural sac while including the vessel in the ligature, should be most carefully borne in mind.

Collateral Circulation.—Allan Burns demonstrated, on the dead subject, the possibility of the establishment of the collateral circulation after ligature of the innominate

artery, by tying and dividing that artery. He then found that 'Even coarse injection, impelled into the aorta, passed freely by the anastomosing branches into the arteries of the right arm, filling them and all the vessels of the head completely.'* The branches by which this circulation is carried on are numerous; thus, all the communications across the middle line between the branches of the carotid arteries of opposite sides are available for the supply of blood to the right side of the head and neck; the anastomosis between the costocervical of the subclavian and the first aortic intercostal (see *infra* on the collateral circulation after obliteration of the thoracic aorta) brings the blood, by a free and direct course, into the right subclavian; the numerous connexions between the intercostal arteries and the branches of the axillary and internal mammary arteries assist in the supply of blood to the right arm, while the inferior epigastric from the external iliac, by means of its anastomosis with the internal mammary, compensates for any deficiency in the vascularity of the wall of the chest.

ARTERIES OF THE HEAD AND NECK

The principal arteries of the head and neck are the two common carotids; they ascend in the neck and each divides into two branches, viz. (1) the external carotid, supplying the exterior of the head, the face, and the greater part of the neck; (2) the internal carotid, supplying to a great extent the parts within the cranial and orbital cavities.

COMMON CAROTID ARTERIES

The common carotid arteries differ in length and in their mode of origin. The *right* begins at the bifurcation of the innominate artery behind the sternoclavicular joint and is confined to the neck. The *left* springs from the highest part of the arch of the aorta to the left of, and on a plane posterior to, the innominate artery, and therefore consists of a thoracic and a cervical portion.

The thoracic portion of the left common carotid artery ascends from the arch of the aorta through the superior mediastinal cavity to the level of the left sternoclavicular joint, where it is continuous with the cervical portion.

Relations.—*In front*, it is separated from the manubrium sterni by the Sternohyoideus and Sternothyreoideus, the anterior portions of the left pleura and lung, the left innominate vein, and the remains of the thymus; *behind* it are the trachea, œsophagus, left recurrent nerve, and thoracic duct. To its *right side* below, is the innominate artery, and above, the trachea, the inferior thyroid veins, and the remains of the thymus, to its *left side* are the left vagus and phrenic nerves, the left pleura and lung. The left subclavian artery is posterior and slightly lateral to it.

The cervical portions of the common carotid arteries resemble each other so closely that one description will apply to both (fig. 615). Each passes obliquely upwards, from behind the sternoclavicular articulation, to the level of the upper border of the thyroid cartilage, where it divides into the external and internal carotid arteries. Behind the point of division of the artery is a small reddish brown, ductless gland, termed the *glomus caroticum* (carotid body).

At the lower part of the neck the two arteries are separated from each other by a very narrow interval which contains the trachea; but at the upper part, the thyroid gland, the larynx, and the pharynx project forwards between the two vessels. The common carotid artery is contained in a sheath, which is derived from the fascia colli (deep cervical fascia) and encloses also the internal jugular vein and vagus nerve, the vein lying lateral to the artery, and the nerve between the artery and vein, on a plane posterior to both. In the sheath, each of these structures has a separate fibrous investment.

Relations.—At the lower part of the neck the common carotid artery is very deeply seated, being covered by the integument, superficial fascia, Platysma, deep cervical fascia, and the Sternocleidomastoideus, Sternohyoideus, Sternothyreoideus, and Omohyoideus; in the upper part of its course it is more superficial, being covered merely by the integument, the superficial fascia, Platysma, deep

* *Surgical Anatomy of the Head and Neck*, p. 62.

cervical fascia, and the medial margin of the Sternocleidomastoideus. When the latter muscle is drawn backwards, the artery is seen to be contained in a triangular space, the *carotid triangle*, bounded behind by the Sternocleidomastoideus, above by the Stylohyoideus and posterior belly of the Digastricus, and below by the superior belly of the Omohyoideus. This part of the artery is crossed obliquely, from its medial to its lateral side, by the sternocleidomastoid branch of the superior

FIG. 615.—Superficial dissection of the right side of the neck, showing the carotid and subclavian arteries.

thyroid artery. In front of its sheath is the descending branch of the hypoglossal nerve, this branch being joined by the descendens cervicalis nerve which springs from the second and third cervical nerves and crosses the vessel obliquely: sometimes the descending branch of the hypoglossal nerve is contained within the sheath of the vessels. The superior thyroid vein crosses the artery near its termination, and the middle thyroid vein a little below the level of the cricoid cartilage: the anterior jugular vein crosses the artery just above the clavicle, but is separated from it by the Sternohyoideus and Sternothyroideus. *Behind* the artery is separated from the transverse processes of the cervical vertebrae by the Longus

colli and Longus capitis, the sympathetic trunk being interposed between the artery and the muscles. The inferior thyroid artery crosses behind the lower part of the vessel; below the level of the sixth cervical vertebra the left common carotid artery is in relation posteriorly with the vertebral artery and the cervical part of the thoracic duct. *Medially*, it is in relation with the œsophagus, trachea, and thyroid gland (which overlaps it), the inferior thyroid artery and recurrent nerve being interposed; higher up, with the larynx and pharynx. *Lateral* to the artery are the internal jugular vein and vagus nerve.

At the lower part of the neck, the right recurrent nerve crosses obliquely behind the artery; the right internal jugular vein diverges from the artery, but the left approaches and often overlaps the lower part of the artery.

Peculiarities.—In about 12 per cent. of cases the *right common carotid* arises above the level of the upper border of the sternoclavicular articulation. It may arise as a separate branch from the arch of the aorta, or in conjunction with the left carotid. The *left common carotid* varies in its origin more frequently than the right. In the majority of abnormal cases it arises with the innominate artery; if that artery be absent, the two carotids arise usually by a single trunk. It is rarely joined with the left subclavian, except in cases of transposition of the aortic arch.

Division of the artery may occur at or above the level of the hyoid bone; more rarely it occurs below the usual level, opposite the middle of the larynx, or the lower border of the cricoid cartilage; one case is related by Morgagni, where the artery was only 4 cm. in length and divided at the root of the neck. Very rarely, the common carotid ascends in the neck without undergoing subdivision, either the external or the internal carotid being wanting. In a few cases the common carotid has been found to be absent, the external and internal carotids arising directly from the arch of the aorta; this peculiarity existed on both sides in some instances, on one side only in others.

The common carotid usually supplies no branch previous to its bifurcation; but it may give origin to the vertebral, the superior thyroid or its laryngeal branch, the ascending pharyngeal, the inferior thyroid, or the occipital.

Applied Anatomy.—Aneurysms are not commonly met with on the common carotid; when they do occur they are usually situated low down at the root of the neck, or just below the point of bifurcation of the vessel. They do not often assume a large size, and are more commonly found on the right side. As they increase in size they displace the trachea and larynx, and therefore dyspnoea becomes a prominent symptom. Dysphagia also may be present from pressure on the œsophagus, especially if the aneurysm is on the left side; and pressure on the recurrent nerve may produce hoarseness and laryngeal cough. Pressure on the sympathetic will cause pupillary changes—dilatation of the pupil when the sympathetic is irritated or the arterial blood-supply to the eye is lessened, contraction when the sympathetic has become paralysed; sympathetic irritation may also cause unilateral sweating of the head and neck. Pressure on the superficial branches of the cervical plexus may give rise to pain in the head, face, and neck; pressure on the vagus to irregular action of the heart and to asthmatic attacks. It is important to bear in mind that an enlarged lymph gland in the superior carotid triangle, receiving a transmitted pulsation from the carotid artery, may simulate aneurysm of that vessel, but may be distinguished from it by the character of the pulsation, which is not expansile.

Embolism of the left common carotid artery, or the thrombosis that may follow injury to the wall of the vessel by penetrating gunshot wounds of the neck, have been known to produce aphasia by interference with the blood-supply of the brain.

Digital compression of the common carotid is sometimes required, and is best effected by compressing the vessel with the thumb against the anterior tubercle of the transverse process of the sixth cervical vertebra (p. 164).

Ligature of the common carotid artery may be necessary in a case of wound of that vessel or its branches, in aneurysm, or in a case of pulsating tumour of the orbit or skull. If the wound involves the trunk of the common carotid, it will be necessary to tie the artery above and below the wounded part. In cases of aneurysm, the whole of the artery is accessible, and any part of it may be tied. When the case is such as to allow of a choice being made, the upper part of the carotid should be selected as the spot upon which to place a ligature, for the lower part of the vessel is placed very deeply in the neck, and covered by three layers of muscles; moreover, on the left side, the internal jugular vein, in the great majority of cases, passes obliquely in front of it. The part of the vessel which is most favourable for the operation is that opposite the level of the cricoid cartilage. It occasionally happens that the carotid artery bifurcates below its usual position: if the artery be exposed at its point of bifurcation, both divisions of the vessel should be tied near their origin, in preference to tying the trunk of the artery near its termination; and if, in consequence of the entire absence of the common carotid, or from its early division, two arteries, the external and internal carotids, are met with, the ligature should be placed on that vessel which is found on compression to be connected with the diseased area.

In this operation, the direction of the vessel and the anterior margin of the Sternocleidomastoideus are the chief guides to its performance. The patient should be placed

on his back with the head extended and turned slightly to the opposite side: an incision is to be made, 7 or 8 cm. long, in the direction of the anterior border of the Sternocleidomastoideus, so that the centre corresponds to the level of the cricoid cartilage. After dividing the integument, superficial fascia, Platysma, and deep fascia, the margins of the wound are held asunder by retractors, and the ramus descendens hypoglossi is now exposed, and must be avoided. The sheath of the vessel is to be raised by forceps, and opened to a small extent over the artery at its medial side. The internal jugular vein may present itself alternately distended and relaxed, and must be carefully avoided. The aneurysm needle is passed from the lateral aspect, care being taken to keep the needle in close contact with the artery, and thus avoid the risk of injuring the internal jugular vein, or including the vagus nerve. Before the ligature is tied, it should be ascertained that nothing but the artery is included in it.

Ligature of the common carotid near the root of the neck is sometimes required in cases of aneurysm of the upper part of the artery, especially if the sac is of large size. It is best performed by dividing the sternal origin of the Sternocleidomastoideus, but may be done in some cases, if the aneurysm is not of very large size, by an incision along the anterior border of the muscle, extending down to the sternoclavicular articulation, and by then retracting the muscle. Beneath it are two additional muscular layers, viz.: the Sternohyoideus and the Sternothyroideus; these have to be split and retracted, one after the other, before the sheath of the vessel is reached. In doing this, care must be taken not to wound the anterior jugular vein, which crosses the Sternohyoideus to reach the external jugular or subclavian vein. The sheath must be opened on its medial or tracheal side, so as to avoid the internal jugular vein. Special care is necessary on the left side, where the artery is commonly overlapped by the vein; on the right side there is usually an interval between the artery and the vein, and the risk of wounding the latter is less.

The common carotid artery, being a long vessel without any branches, is particularly suitable for the performance of Brasdor's operation for the cure of an aneurysm of the lower part of the vessel. Brasdor's procedure consists in ligaturing the artery on the distal side of the aneurysm, and in the case of the common carotid there are no branches given off from the vessel between the aneurysm and the site of the ligature; hence the flow of blood through the sac of the aneurysm is diminished, and cure takes place in the usual way by the deposit of laminated fibrin.

Collateral Circulation.—After ligature of the common carotid, the collateral circulation can be perfectly established by the free communication which exists between the carotid arteries of opposite sides, both without and within the cranium, and by enlargement of the branches of the subclavian artery. The chief communications outside the skull take place between the superior and inferior thyroid arteries, and between the profunda cervicis and ramus descendens of the occipital: the vertebral takes the place of the internal carotid within the cranium.

EXTERNAL CAROTID ARTERY

The **external carotid artery** (fig. 615) begins opposite the upper border of the thyroid cartilage, at the level of the disc between the third and fourth cervical vertebræ, and, taking a slightly curved course, passes upwards and forwards, and then inclines backwards to a point behind the neck of the mandible, where it divides into the superficial temporal and internal maxillary arteries. It diminishes rapidly in size, owing to the number and large size of the branches given off from it. In the child, it is somewhat smaller than the internal carotid; but in the adult, the two vessels are of nearly equal size. At its origin, this artery is more superficial, and placed nearer the middle line than the internal carotid artery, and is contained within the carotid triangle.

Relations.—The external carotid artery is covered by the skin, superficial fascia, Platysma, deep fascia, and anterior margin of the Sternocleidomastoideus; it is crossed by the Digastricus and Stylohyoideus, the hypoglossal nerve, the lingual, ranine and common facial veins, and sometimes by the superior thyroid veins; higher up it passes into the substance of the parotid gland, where it lies deep to the facial nerve and the junction of the superficial temporal and internal maxillary veins. Medial to it are the hyoid bone, the wall of the pharynx, the superior laryngeal nerve, and a portion of the parotid gland. Lateral to it, in the lower part of its course, is the internal carotid artery. It is separated from the internal carotid by the Styloglossus and Stylopharyngeus muscles, the glossopharyngeal nerve, the pharyngeal branch of the vagus nerve, and part of the parotid gland.

Applied Anatomy.—Ligature of the external carotid may be required in cases of wound of this vessel, or of its branches when these cannot be tied, and in some cases of pulsating tumours of the scalp or face. It is also done as a preliminary measure to

excision of the maxilla. The seat of election for ligature is between the origins of its superior thyroid and lingual branches, about a finger's breadth below the tip of the greater cornu of the hyoid bone. To tie the vessel, an incision is made from the angle of the mandible to the upper border of the thyroid cartilage, and the superficial tissues and the deep fascia divided. The anterior border of the Sternocleidomastoideus must be retracted and the lower border of the parotid gland raised, so as to expose the tendon of the Digastricus and the hypoglossal nerve, which cross the artery. The great difficulty in doing this is due to the plexus of veins derived from the superior thyroid and lingual veins, which overlie the artery: if necessary, these must be ligatured and divided. Care must be taken not to mistake the lingual and external maxillary arteries, when they arise by a common trunk, as they sometimes do, for the external carotid artery. The needle is to be passed from the lateral to the medial side of the vessel, carefully avoiding the superior laryngeal nerve, which lies in close proximity to the artery.

Collateral Circulation.—The circulation is re-established by the free communication between most of the large branches of the artery (external maxillary, lingual, superior thyroid, occipital) and the corresponding arteries of the opposite side, and by the anastomosis of its branches with those of the internal carotid artery, and of the occipital artery with branches of the subclavian, &c.

BRANCHES OF THE EXTERNAL CAROTID ARTERY (fig. 616)

The branches of the external carotid artery are :

- | | | |
|--------------------------|-------------------------|--------------------------|
| 1. Superior thyroid. | 4. External maxillary. | 7. Superficial temporal. |
| 2. Ascending pharyngeal. | 5. Occipital. | 8. Internal maxillary. |
| 3. Lingual. | 6. Posterior auricular. | |

1. The **superior thyroid artery** (fig. 615) arises from the external carotid artery just below the level of the greater cornu of the hyoid bone and ends in the thyroid gland.

FIG. 616.—Plan of the branches of the external carotid artery.

Relations.—From its origin beneath the anterior border of the Sternocleidomastoideus it runs upwards and forwards for a short distance in the carotid triangle, where it is covered by the skin, Platysma, and fascia; it then arches downwards beneath the Omohyoideus, Sternohyoideus, and Sternothyroideus. To its medial side are the Constrictor pharyngis inferior and the external branch of the superior laryngeal nerve.

Branches.—It distributes twigs to the adjacent muscles, and branches to the thyroid gland; it anastomoses with its fellow of the opposite side, and with the inferior thyroid arteries. The branches to the gland are generally two in number, an anterior and a posterior; the anterior and larger branch supplies principally the anterior surface; on the isthmus of the gland it anastomoses with the corresponding artery of the opposite side; the posterior branch descends on the posterior surface of the gland and anastomoses with the inferior thyroid artery.

Besides the arteries distributed to the muscles and to the thyroid gland, the superior thyroid artery supplies the following branches :

- | | |
|----------------------|---------------------|
| Hyoid. | Superior laryngeal. |
| Sternocleidomastoid. | Cricothyroid. |

The **hyoid branch** is small and runs along the lower border of the hyoid bone beneath the Thyrohyoideus and anastomoses with the vessel of the opposite side.

The **sternocleidomastoid branch** runs downwards and lateralwards across the sheath of the common carotid artery, and enters the Sternocleidomastoideus muscle; it frequently arises as a separate branch from the external carotid artery.

The **superior laryngeal artery**, larger than either of the preceding, accompanies the internal laryngeal branch of the superior laryngeal nerve, beneath the Thyro-hyoideus; it pierces the hyothyroid membrane, and supplies the muscles, mucous membrane and glands of the larynx, anastomosing with the artery of the opposite side, and with the inferior laryngeal branch of the inferior thyroid artery.

The **cricothyroid branch** is small and runs transversely across the cricothyroid membrane, communicating with the artery of the opposite side.

Applied Anatomy.—The superior thyroid, or one of its branches, is often divided in cases of cut throat, giving rise to considerable hæmorrhage. In such cases, the artery should be secured, the wound being enlarged for that purpose, if necessary. The operation may be easily performed, the artery being very superficial, and the only structures of importance covering it being a few small veins. The superior thyroid artery has been ligatured in cases of bronchocele, but the collateral circulation between this vessel and the artery of the opposite side, and the inferior thyroid, is so free that the operation has been given up, especially as better results are obtained by other means.

The position of the sternocleidomastoid branch is of importance in connexion with the operation of ligature of the common carotid artery. It crosses and lies on the sheath of this vessel and may chance to be wounded in opening the sheath. The position of the cricothyroid branch should be remembered, as it may prove the source of troublesome hæmorrhage during the operation of laryngotomy.

2. The **ascending pharyngeal artery** (fig. 621), the smallest branch of the external carotid artery, is a long slender vessel, deeply seated in the neck. It arises close to the origin of the external carotid, and ascends vertically between the internal carotid and the side of the pharynx to the under surface of the base of the skull, lying on the Longus capitis; it anastomoses freely with the ascending palatine branch of the external maxillary artery.

Its branches are :

Pharyngeal.

Posterior meningeal.

Inferior tympanic.

The **pharyngeal branches** are three or four in number. Two of these descend to supply the Constrictores pharyngis medius and inferior and the Stylopharyngeus, ramifying in their substance and in the mucous membrane lining them. A branch of variable size is distributed to the palate, and may take the place of the ascending palatine branch of the external maxillary artery, when that vessel is small. It passes inwards upon the Constrictor pharyngis superior, sends branches to the soft palate and tonsil, and supplies a twig to the auditory tube.

The **inferior tympanic artery** is a small branch which passes through the inferior tympanic canaliculus of the temporal bone, in company with the tympanic branch of the glossopharyngeal nerve, to supply the medial wall of the tympanic cavity and anastomose with the other tympanic arteries.

The **meningeal branches** are several small vessels which supply the dura mater. One, the *posterior meningeal*, enters the cranium through the jugular foramen; a second passes through the foramen lacerum; and occasionally a third through the canal for the hypoglossal nerve.

Numerous small vessels supply the Longi capitis and colli, the sympathetic trunk, the hypoglossal and vagus nerves, and the lymph-glands; they anastomose with the ascending cervical and vertebral arteries.

Applied Anatomy.—The ascending pharyngeal artery has been wounded from the throat; in one case the stem of a tobacco-pipe was driven into the vessel and caused fatal hæmorrhage.

3. The **lingual artery** (fig. 621) arises from the external carotid between the superior thyroid and external maxillary; it first runs obliquely upwards and medialwards to the greater cornu of the hyoid bone; it then curves downwards and forwards, forming a loop which is crossed by the hypoglossal nerve, and passing beneath the Digastricus and Stylohyoideus, it runs horizontally forwards, beneath the Hyoglossus, and finally, ascending almost perpendicularly to the tongue, it turns forwards on its lower surface as far as the tip.

Relations.—Its first portion is superficial, and is contained within the carotid triangle; it rests upon the Constrictor pharyngis medius, and is covered by the Platysma and the fascia of the neck. Its second portion also lies upon the

Constrictor pharyngis medius, being covered at first by the tendon of the Digastricus and by the Stylohyoideus, and afterwards by the Hyoglossus. Its third portion lies between the Hyoglossus and Genioglossus. The fourth or terminal part, under the name of the *arteria profunda linguæ* (ranine artery), runs along the inferior surface of the tongue to its tip, covered only by the mucous membrane; above it is the Longitudinalis inferior, and medial to it the Genioglossus. The hypoglossal nerve crosses the first part of the lingual artery, but is separated from the second part by the Hyoglossus.

The branches of the lingual artery are :

Hyoid.

Rami dorsales linguæ.

Sublingual.

A. profunda linguæ.

The **hyoid branch** runs along the upper border of the hyoid bone, supplying the muscles attached to it and anastomosing with its fellow of the opposite side.

The **rami dorsales linguæ** consist usually of two or three small branches; they arise beneath the Hyoglossus, ascend to the posterior part of the dorsum of the tongue, and supply its mucous membrane, the glossopalatine arch, the tonsil, soft palate, and epiglottis; they anastomose with the vessels of the opposite side.

The **sublingual artery** arises at the anterior margin of the Hyoglossus, and runs forward between the Genioglossus and Mylohyoideus to the sublingual gland. It supplies the gland and gives branches to the Mylohyoideus and neighbouring muscles, and to the mucous membrane of the mouth and gums. One branch runs behind the alveolar part of the mandible in the substance of the gum to anastomose with a similar artery from the other side; another pierces the Mylohyoideus and anastomoses with the submental branch of the external maxillary artery.

The **arteria profunda linguæ** (ranine artery) is the terminal portion of the lingual artery; it pursues a tortuous course and runs along the under surface of the tongue at the side of the frenulum linguæ, below the Longitudinalis inferior, and above the mucous membrane; it lies on the lateral side of the Genioglossus, accompanied by the lingual nerve.

Applied Anatomy.—The lingual artery is not infrequently divided near its origin in cases of cut throat; while severe hæmorrhage, which cannot be restrained by ordinary means, may ensue from a wound, or deep ulcer, of the tongue. In the former case, the primary wound may be enlarged if necessary, and the bleeding vessel secured; in the latter, it has been suggested that the lingual artery should be tied near its origin.

Ligature of the lingual artery has been practised occasionally as a preliminary measure to removal of the tongue. The operation is a difficult one on account of the depth of the artery, the number of important parts by which it is surrounded, and its occasional irregularity of origin. An incision is to be made in a curved direction from a finger's breadth behind the symphysis menti downwards to the cornu of the hyoid bone, and then upwards to near the angle of the mandible. Care must be taken not to carry this incision too far backwards, for fear of endangering the anterior facial vein. In the first incision the skin, superficial fascia, and Platysma will be divided, and the deep fascia displayed. This is then to be incised and the submaxillary gland exposed and pulled upwards. A triangular space is now seen, bounded in front by the posterior border of the Mylohyoideus, below and behind by the tendon of the Digastricus, and above by the hypoglossal nerve. The floor of the space is formed by the Hyoglossus, beneath which the artery lies. The parts are to be drawn forwards by a blunt hook inserted beneath the tendon of the Digastricus, and the fibres of the Hyoglossus cut through horizontally just above the Digastricus. The artery will then be exposed; and in passing the aneurysm needle, care must be taken not to open the pharynx. The hypoglossal nerve must also be avoided.

Troublesome hæmorrhage may occur in the division of the frenulum linguæ in children, if the aa. profundæ linguæ, which lie one on either side of it, be wounded. The operation should always be performed with a pair of blunt-pointed scissors, and the mucous membrane alone divided by a very superficial cut, which cannot endanger any vessel. Any further liberation of the tongue which may be necessary can be effected by tearing.

4. The **external maxillary artery** (facial artery) (fig. 617) arises in the carotid triangle a little above the lingual artery, and sheltered by the ramus of the mandible, passes obliquely up beneath the Digastricus and Stylohyoideus, over which it arches to enter a groove on the posterior border of the submaxillary gland. It then curves upwards over the body of the mandible at the anteroinferior angle of the Masseter; passes forwards and upwards across the cheek to the angle of the mouth, then ascends along the side of the nose,

and ends at the medial palpebral commissure, under the name of the *angular artery*. The external maxillary artery is remarkably tortuous: in the neck to accommodate itself to the movements of the pharynx during deglutition, and on the face to the movements of the mandible, lips, and cheeks.

Relations.—*In the neck*, its origin is superficial, being covered by the integument, Platysma, and fascia; it then passes beneath the Digastricus and Stylohyoideus muscles and part of the submaxillary gland, and frequently beneath the hypoglossal nerve. It lies upon the Constrictores pharyngis medius and superior, the latter of which separates it, at the summit of its arch, from the lower and posterior part of the tonsil. *On the face*, where it passes over the body of the mandible, it is

FIG. 617.—The arteries of the face and scalp.

comparatively superficial, lying immediately beneath the Platysma. In its course over the face, it is covered by the integument, the fat of the cheek, and, near the angle of the mouth, by the Platysma, Risorius, and Zygomaticus. It rests on the Buccinator and Caninus, and passes either over or under the infraorbital head of the Quadratus labii superioris. The anterior facial vein lies posterior to the artery, and takes a more direct course across the face, where it is separated from the artery by a considerable interval; in the neck it lies superficial to the artery. The branches of the facial nerve cross the artery from behind forwards.

The branches of the external maxillary artery may be divided into two sets: those given off in the neck (cervical), and those on the face (facial).

Cervical branches.

Ascending palatine.
Tonsillar.
Glandular.
Submental.

Facial branches.

Inferior labial.
Superior labial.
Lateral nasal.
Angular.

The **ascending palatine artery** (fig. 621) arises close to the origin of the external maxillary artery and passes up between the Styloglossus and Stylopharyngeus to the side of the pharynx, along which it is continued between the Constrictor pharyngis superior and the Pterygoideus internus towards the base of the skull. Near the Levator veli palatini it divides into two branches: one follows the course of this muscle, and, winding over the upper border of the Constrictor pharyngis superior, supplies the soft palate and the palatine glands, anastomosing with its fellow of the opposite side and with the descending palatine branch of the internal maxillary artery; the other pierces the Constrictor pharyngis superior and supplies the palatine tonsil and auditory tube, anastomosing with the tonsillar and ascending pharyngeal arteries.

The **tonsillar branch** (fig. 621) ascends between the Pterygoideus internus and Styloglossus, and then along the side of the pharynx; it perforates the Constrictor pharyngis superior and ramifies in the palatine tonsil and root of the tongue.

The **glandular branches** are three or four large vessels, which supply the submaxillary gland, the neighbouring muscles, the submaxillary lymph-glands, and the skin.

The **submental artery**, the largest of the cervical branches, springs from the external maxillary artery just as that vessel quits the submaxillary gland: it runs forwards upon the Mylohyoideus, below the body of the mandible, and beneath the Digastricus. It supplies the surrounding muscles, and anastomoses with the sublingual artery and with the mylohyoid branch of the inferior alveolar; at the chin it turns upwards over the inferior border of the mandible and divides into a superficial and a deep branch. The superficial branch passes between the integument and Quadratus labii inferioris, and anastomoses with the inferior labial artery; the deep branch runs between the muscle and the bone, supplies the lip, and anastomoses with the inferior labial and mental arteries.

The **inferior labial artery** (inferior coronary artery) arises near the angle of the mouth; it passes upwards and forwards beneath the Triangularis, and, penetrating the Orbicularis oris, runs in a tortuous course along the edge of the lower lip between this muscle and the mucous membrane. It supplies the glands, mucous membrane and muscles of the lower lip; and anastomoses with the artery of the opposite side, and with the mental branch of the inferior alveolar artery.

The **superior labial artery** (superior coronary artery) is larger and more tortuous than the inferior. It follows a similar course along the edge of the upper lip, lying between the mucous membrane and the Orbicularis oris, and anastomoses with the artery of the opposite side. It supplies the upper lip, and gives off a *septal branch* which ramifies on the nasal septum as far as the point of the nose, and an *alar branch* which supplies the ala of the nose.

The **lateral nasal branch** is derived from the external maxillary, as that vessel ascends along the side of the nose. It supplies the ala and dorsum of the nose, anastomosing with its fellow, with the septal and alar branches, with the dorsal nasal branch of the ophthalmic, and with the infraorbital branch of the internal maxillary.

The **angular artery** is the terminal part of the external maxillary; it ascends to the medial angle of the orbit, imbedded in the fibres of the angular head of the Quadratus labii superioris, and accompanied by the angular vein. On the cheek it anastomoses with the infraorbital, and, after supplying the lacrimal sac and Orbicularis oculi, ends by anastomosing with the dorsal nasal branch of the ophthalmic artery.

The anastomoses of the external maxillary artery are very numerous, not only with the branches of the vessel of the opposite side, but, *in the neck*, with the sublingual branch of the lingual, with the ascending pharyngeal, and with the palatine branch of the internal maxillary; *on the face*, with the mental branch of the inferior alveolar, the transverse facial branch of the superficial temporal, the infraorbital branch of the internal maxillary, and the dorsal nasal branch of the ophthalmic.

Peculiarities.—The external maxillary artery not infrequently arises in common with the lingual. It varies in its size and in the extent to which it supplies the face; it occasionally ends as the submental, and not infrequently extends only as high as the angle of the mouth or nose. The deficiency is then compensated for by enlargement of one of the neighbouring arteries.

Applied Anatomy.—The passage of the external maxillary artery over the body of the mandible would appear to afford a favourable position for the application of pressure.

in cases of hæmorrhage from the lips; but such application is useless, except for a very short time, on account of the free communication of the artery with its fellow, and with numerous branches from different sources. In a wound involving the lip, it is better to seize the part between the fingers, and evert it, when the bleeding vessel may be at once secured with pressure-forceps. In order to prevent hæmorrhage during the removal of growths from the lip, the latter should be compressed on either side between the fingers and thumb, or by a pair of specially devised clamp-forceps, while the surgeon excises the diseased part. In order to stop hæmorrhage when the lip has been divided in an operation, it is necessary, when closing the wound, to pass the sutures through the cut edges, almost as deep as its mucous surface; by these means, not only are the cut surfaces more neatly and securely adapted to each other, but the possibility of hæmorrhage is prevented by including the divided artery in the suture. If, on the contrary, the suture be passed through merely the cutaneous portion of the wound, hæmorrhage occurs into the cavity of the mouth. The student should observe that the angular artery ascends on the nasal side of the lacrimal sac; in operating for fistula lacrimonalis, the sac should always be opened on its lateral side, in order to avoid this vessel.

 The occipital artery (fig. 617) arises from the posterior part of the external carotid, opposite the external maxillary artery, and near the lower margin of the posterior belly of the Digastricus; it ends in the posterior part of the scalp.

Relations.—At its origin, it is covered by the posterior belly of the Digastricus and the Stylohyoideus, and the hypoglossal nerve winds round it from behind forwards: higher up, it crosses the internal carotid artery, the internal jugular vein, and the vagus and accessory nerves. It next ascends along the lower border of the posterior belly of the Digastric to the interval between the transverse process of the atlas and the mastoid process of the temporal bone, and passes horizontally backwards, grooving the surface of the latter bone, being covered by the Sternocleidomastoideus, Splenius capitis, Longissimus capitis, and Digastricus, and resting upon the Rectus capitis lateralis, Obliquus superior, and Semispinalis capitis. It then runs vertically upwards, pierces the fascia connecting the cranial attachment of the Trapezius with the Sternocleidomastoideus, and ascends in a tortuous course in the superficial fascia of the scalp, where it divides into numerous branches. Its terminal portion is accompanied by the greater occipital nerve.

The branches of the occipital artery are:

Sternocleidomastoid.	Auricular.	Meningeal.
Mastoid.	Muscular (ramus descendens).	Occipital.

The **sternocleidomastoid branch** generally arises from the beginning of the occipital artery, but sometimes springs directly from the external carotid. It passes downwards and backwards over the hypoglossal nerve, and enters the substance of the Sternocleidomastoideus, in company with the accessory nerve; it anastomoses with the sternocleidomastoid branch of the superior thyroid artery.

The **mastoid branch**, small in size and sometimes absent, enters the cranial cavity through the mastoid foramen; it gives branches to the mastoid cells and dura mater and anastomoses with the middle meningeal artery.

The **auricular branch** supplies the back of the concha and anastomoses with the posterior auricular artery.

Muscular branches are supplied to the Digastricus, Stylohyoideus, Splenius, and Longissimus capitis. A large vessel, named the *ramus descendens* (arteria princeps cervicis) (fig. 621), runs downwards on the back of the neck, and divides into a superficial and a deep portion. The superficial portion passes beneath the Splenius, giving off branches which pierce that muscle to supply the Trapezius and anastomose with the ascending branch of the transverse cervical artery; the deep portion descends between the Semispinales capitis and colli, and anastomoses with the vertebral and with the arteria profunda cervicalis, a branch of the costocervical trunk. The anastomosis between these vessels assists in establishing the collateral circulation after ligature of the common carotid or subclavian artery.

The **meningeal branches** ascend with the internal jugular vein, and enter the skull through the jugular foramen and condyloid canal, to supply the dura mater in the posterior fossa.

The **occipital branches**, the terminal branches, are distributed to the scalp, and reach as high as the vertex of the skull; they are very tortuous, and lie between the skin and the Occipitalis, anastomosing with the artery of the opposite side and with the posterior auricular and temporal arteries, and supplying the Occipitalis.

the skin, and the pericranium. One of the terminal branches may give off a meningeal twig which passes through the parietal foramen.

6. The **posterior auricular artery** (fig. 617) is small and arises from the external carotid immediately above the *Digastricus* and *Stylohyoideus*. It ascends, under cover of the parotid gland, on the styloid process of the temporal bone, to the groove between the cartilage of the auricle and the mastoid process, where it divides into auricular and occipital branches.

In addition to supplying small branches to the *Digastricus*, *Stylohyoideus*, *Sternocleidomastoideus*, and parotid gland, this vessel gives off the three following branches :

Stylomastoid.

Auricular.

Occipital.

The **stylomastoid artery** enters the stylomastoid foramen and supplies the tympanic cavity, the tympanic antrum, the mastoid cells, and the semicircular canals. In the young subject a branch from this vessel forms, with the anterior tympanic artery from the internal maxillary, a vascular circle which surrounds and supplies small vessels to the tympanic membrane. It anastomoses with the superficial petrosal branch of the middle meningeal artery by a twig which enters the hiatus canalis facialis.

The **auricular branch** ascends beneath the *Auricularis posterior*, and ramifies on the back of the auricle ; some of its branches curve round the margin of the auricle and others pierce it, to supply its lateral surface. It anastomoses with the parietal and anterior auricular branches of the superficial temporal artery.

The **occipital branch** passes backwards over the *Sternocleidomastoideus* to the *Occipitalis* muscle and the scalp above and behind the ear ; it anastomoses with the occipital artery.

7. The **superficial temporal artery** (fig. 617), the smaller terminal branch of the external carotid, begins in the substance of the parotid gland, behind the neck of the mandible, and crosses over the posterior root of the zygomatic process of the temporal bone ; about 5 cm. above this process it divides into a frontal and a parietal branch.

Relations.—As it crosses the zygomatic process, it is covered by the *Auricularis anterior* muscle, and by a dense fascia ; it is crossed by the temporal and zygomatic branches of the facial nerve and is accompanied by the auriculotemporal nerve, which lies immediately behind it.

It supplies some twigs to the parotid gland, the temporomandibular joint, and the *Masseter* muscle, and gives off the following branches :

Transverse facial.

Zygomatico-orbital.

Frontal.

Anterior auricular.

Middle temporal.

Parietal.

The **transverse facial artery** is given off from the superficial temporal before that vessel quits the parotid gland ; it runs forwards through the substance of the gland, passes transversely across the side of the face between the parotid duct and the lower border of the zygomatic arch and divides into numerous branches which supply the parotid gland and duct, the *Masseter*, and the integument, and anastomose with the external maxillary, masseteric, buccinator, and infraorbital arteries. This vessel rests on the *Masseter*, and is accompanied by one or two branches of the facial nerve.

The **anterior auricular branches** are distributed to the lobule and anterior portion of the auricle, and to the external meatus ; they anastomose with the posterior auricular artery.

The **zygomatico-orbital artery**, sometimes a branch of the middle temporal artery, runs along the upper border of the zygomatic arch between the two layers of the temporal fascia to the lateral angle of the orbit. It supplies the *Orbicularis oculi* and anastomoses with the lacrimal and palpebral branches of the ophthalmic artery.

The **middle temporal artery** arises immediately above the zygomatic arch, and, perforating the temporal fascia, gives branches to the *Temporalis* muscle ; it anastomoses with the deep temporal branches of the internal maxillary artery.

The **frontal branch** runs tortuously upwards and forwards towards the frontal tuberosity ; it supplies the muscles, skin, and pericranium in this region, and anastomoses with the supraorbital and frontal arteries.

The *parietal branch*, larger than the frontal, curves upwards and backwards on the side of the head, lying superficially to the temporal fascia, and anastomosing with its fellow of the opposite side, and with the posterior auricular and occipital arteries.

Applied Anatomy.—As the superficial temporal artery crosses the zygomatic process, it lies beneath the skin and fascia, and its pulsations may be readily felt during the administration of an anæsthetic, or under circumstances where the radial pulse is not available; it may be easily compressed against the bone in order to check bleeding from the temporal region of the scalp. When a flap is raised from this part of the head, for trephining, the incision should be shaped like a horseshoe, with its convexity upwards, so that the flap shall contain the superficial temporal artery, which ensures a sufficient supply of blood. The same principle is applied, as far as possible, in making incisions to raise flaps in other parts of the scalp.

8. The *internal maxillary artery* (figs. 618, 619), the larger terminal branch of the external carotid, arises behind the neck of the mandible, and is at first imbedded in the substance of the parotid gland; it passes forwards between the ramus of the mandible and the sphenomandibular ligament, and then runs, either superficial or deep to the Pterygoideus externus, to the pterygopalatine fossa. It may be divided into mandibular, pterygoid, and pterygopalatine portions.

The *first or mandibular portion* passes horizontally forwards, between the ramus of the mandible and the sphenomandibular ligament, where it lies parallel to and a little below the auriculotemporal nerve; it crosses the inferior alveolar nerve, and runs along the lower border of the Pterygoideus externus.

The *second or pterygoid portion* runs obliquely forwards and upwards under cover of the ramus of the mandible and the insertion of the Temporalis, superficially to the lower head of the Pterygoideus externus; very frequently it lies beneath this muscle between it and the branches of the mandibular nerve.

The *third or pterygopalatine portion* passes between the two heads of the Pterygoideus externus, and through the pterygomaxillary fissure into the pterygopalatine fossa, where it lies in front of the sphenopalatine ganglion.

The branches of the vessel may be divided into three groups (fig. 619), corresponding with its three portions.

BRANCHES OF THE FIRST OR MANDIBULAR PORTION

Anterior tympanic.
Deep auricular.

Middle meningeal.
Accessory meningeal.

Inferior alveolar.

The *anterior tympanic artery* ascends behind the temporomandibular joint, and enters the tympanic cavity through the petrotympanic fissure; it ramifies upon the tympanic membrane, forming a vascular circle around it with the stylo-mastoid branch of the posterior auricular; it anastomoses with the artery of the pterygoid canal and with the caroticotympanic branch from the internal carotid.

The *deep auricular artery* often arises in common with the anterior tympanic. It ascends in the substance of the parotid gland, behind the temporomandibular joint, pierces the cartilaginous or bony wall of the external acoustic meatus, and supplies its cartilaginous lining and the outer surface of the tympanic membrane; it gives a branch to the temporomandibular joint.

The *middle meningeal artery* is the largest of the meningeal arteries. It ascends between the sphenomandibular ligament and the Pterygoideus externus and between the two roots of the auriculotemporal nerve to the foramen spinosum of the sphenoidal bone, through which it enters the cranial cavity; it then runs forwards in a groove on the great wing of the sphenoidal bone, and divides into two branches, anterior and posterior. The *anterior branch*, the larger, crosses the great wing of this bone, reaches the groove, or canal, in the sphenoidal angle of the parietal bone, and then divides into branches which spread out between the dura mater and internal table of the cranium, some passing upwards as far as the vertex, and others forwards to the occipital region. The *posterior branch* curves backwards on the squamous part of the temporal bone, and, reaching the squamous border of

the parietal bone some distance in front of its mastoid angle, divides into branches which supply the posterior part of the dura mater and cranium. The branches

FIG. 618.—The internal maxillary artery.

FIG. 619.—Plan of branches of internal maxillary artery.

of the middle meningeal artery anastomose with the arteries of the opposite side, and with the anterior and posterior meningeal arteries.

The middle meningeal gives off the following branches within the cranial cavity:
1. Numerous small ganglionic branches supply the semilunar ganglion and the roots of

the trigeminal nerve. 2. A *superficial petrosal branch* enters the hiatus of the facial canal, gives twigs to the facial nerve and tympanic cavity, and anastomoses with the stylomastoid branch of the posterior auricular artery. 3. A *superior tympanic artery* runs in the semicanal for the Tensor tympani, and supplies this muscle and the lining membrane of the canal. 4. *Orbital branches* pass through the superior orbital fissure and anastomose with the lacrimal or other branches of the ophthalmic artery. 5. *Temporal branches* pass through foramina in the great wing of the sphenoid, and anastomose in the temporal fossa with the deep temporal arteries.

Applied Anatomy.—The middle meningeal artery is of considerable surgical importance, as it may be torn in fractures of the temporal region of the skull, or, indeed, by injuries causing separation of the dura mater from the bone without fracture. The injury may be followed by considerable hæmorrhage between the bone and dura mater, which produces symptoms of compression of the brain, and requires trephining for its relief. As the compression implicates the motor region of the cortex, paralysis on the opposite side of the body forms the prominent symptom of the lesion. The anterior branch of this artery crosses the sphenoidal angle of the parietal bone at a point 4 cm. behind the zygomatic process of the frontal bone, and 4·5 cm. above the zygomatic arch. From this point it passes upwards and slightly backwards to the sagittal suture, lying about 1·25 to 2 cm. behind the coronal suture. The posterior branch runs backwards over the squama of the temporal bone. In order to expose the anterior branch of the artery, a point is taken 4 cm. above the zygomatic arch and the same distance behind the zygomatic process of the frontal bone. Here the pin of the trephine is to be applied. A horseshoe-shaped flap, measuring 8 cm. in length and transversely, and consisting of all the structures of the scalp down to and including the pericranium, is first made, with its base just above the zygomatic arch. This flap is reflected and a 2·5 cm. trephine applied. After the circle of bone has been removed, the blood-clot is exposed, and gently got rid of, and if possible the bleeding point must be found and controlled.

The *accessory meningeal branch* may arise from the internal maxillary or the middle meningeal artery. It enters the cranial cavity through the foramen ovale, and supplies the semilunar ganglion and dura mater.

The *inferior alveolar artery* (inferior dental artery) descends with the inferior alveolar nerve to the mandibular foramen on the medial surface of the ramus of the mandible. It runs in the mandibular canal, accompanied by the inferior alveolar nerve, and, opposite the first premolar tooth, divides into two branches, incisor and mental. The *incisor* branch is continued forwards beneath the incisor teeth as far as the middle line, where it anastomoses with the artery of the opposite side; the inferior alveolar artery and its incisor branch give off a few twigs to the mandible, and a series of branches which correspond in number to the roots of the teeth; these enter the minute apertures at the extremities of the roots, and supply the pulp of the teeth. The *mental* branch escapes at the mental foramen, supplies the chin, and anastomoses with the submental and inferior labial arteries. Near its origin the inferior alveolar artery gives off a *lingual* branch which descends with the lingual nerve and supplies the mucous membrane of the mouth. Before the inferior alveolar artery enters the mandibular foramen, it gives off a *mylohyoid* branch which runs in the mylohyoid groove with the mylohyoid nerve, and ramifies on the under surface of the Mylohyoideus.

BRANCHES OF THE SECOND OR PTERYGOID PORTION

Deep temporal.
Pterygoid.

Masseteric.
Buccinator.

The *deep temporal branches*, an anterior and a posterior, ascend between the Temporalis and the pericranium; they supply the muscle, and anastomose with the middle temporal artery; the anterior communicates with the lacrimal artery by means of small branches which perforate the zygomatic bone and great wing of the sphenoidal bone.

The *pterygoid branches*, irregular in their number and origin, supply the Pterygoidei.

The *masseteric artery* is small and passes with the masseteric nerve through the mandibular notch behind the tendon of the Temporalis muscle to the deep surface of the Masseter. It supplies the Masseter muscle, and anastomoses with the masseteric branches of the external maxillary and with the transverse facial artery.

The **buccinator artery** is small and runs obliquely forwards with the buccinator nerve, between the Pterygoideus internus and the insertion of the Temporalis, to the outer surface of the Buccinator muscle, to which it is distributed, anastomosing with branches of the external maxillary and with the infraorbital.

BRANCHES OF THE THIRD OR PTERYGOPALATINE PORTION

Posterior superior alveolar.
Infraorbital.
Descending palatine.

Artery of the pterygoid canal.
Pharyngeal.
Sphenopalatine.

The **posterior superior alveolar artery** (posterior dental artery) is given off from the internal maxillary as that vessel enters the pterygopalatine fossa; it frequently arises in conjunction with the infraorbital artery. Descending upon the infratemporal surface of the maxilla, it divides into numerous branches, some of which enter the alveolar canals to supply the molar and premolar teeth and the lining of the maxillary sinus, while others are continued forwards on the alveolar process to supply the gums.)

The **infraorbital artery** often arises in conjunction with the posterior superior alveolar. It runs along the infraorbital groove and canal with the infraorbital nerve, and emerges with the nerve on the face through the infraorbital foramen, beneath the infraorbital head of the Quadratus labii superioris. While in the canal, it gives off (a) orbital branches which assist in supplying the Rectus inferior and Obliquus inferior and the lacrimal sac, and (b) anterior superior alveolar branches which descend through the anterior alveolar canals to supply the upper incisor and canine teeth and the mucous membrane of the maxillary sinus. On the face, some branches ascend to the medial angle of the orbit and the lacrimal sac, anastomosing with the angular branch of the external maxillary artery; others run towards the nose, anastomosing with the dorsal nasal branch of the ophthalmic; and others descend between the Quadratus labii superioris and the Caninus, and anastomose with the external maxillary, transverse facial, and buccinator arteries.

The remaining branches of the internal maxillary artery arise from that portion of the artery which is contained in the pterygopalatine fossa.

The **descending palatine artery** descends through the pterygopalatine canal with the anterior palatine branch of the sphenopalatine ganglion, and gives off two or three smaller palatine arteries which are transmitted through the lesser palatine canals to supply the soft palate and palatine tonsil, and to anastomose with the ascending palatine artery. The continuation of the vessel is termed the **greater palatine artery**; it emerges on the oral surface of the palate through the greater palatine foramen, runs forwards in a groove near the alveolar border of the hard palate to the incisive canal; its terminal branch passes upwards through this canal, and anastomoses with a branch of the sphenopalatine artery. Branches are distributed to the gums, the palatine glands, and the mucous membrane of the roof of the mouth.

Applied Anatomy.—The position of the descending palatine artery on the hard palate should be borne in mind in performing an operation for the closure of a cleft in the hard palate, as it is in danger of being wounded, and may give rise to formidable hæmorrhage; it has even been found necessary to plug the pterygopalatine canal in order to arrest the bleeding.

The **artery of the pterygoid canal** (Vidian artery), frequently a branch of the descending palatine artery, passes backwards along the pterygoid canal with the corresponding nerve. It is distributed to the upper part of the pharynx and to the auditory tube, and sends into the tympanic cavity a small branch which anastomoses with the other tympanic arteries.

The **pharyngeal branch** is very small; it runs backwards through the pharyngeal canal with the pharyngeal nerve, and is distributed to the roof of the nose and pharynx, to the sphenoidal sinus, and the auditory tube.

The artery of the pterygoid canal and the pharyngeal branch lie on the lateral and medial aspects respectively of the sphenopalatine ganglion, while the trunk of the internal maxillary artery is in front of it.

The **sphenopalatine artery** is really the terminal part of the internal maxillary; it passes through the sphenopalatine foramen into the cavity of the nasal fossa.

posterior part of the superior meatus. Here it gives off its *posterior lateral nasal* branches which ramify over the conchæ and meatuses, anastomose with the ethmoidal arteries and the nasal branches of the descending palatine, and assist in supplying the frontal, maxillary, ethmoidal, and sphenoidal sinuses. Crossing the under surface of the sphenoidal bone, the sphenopalatine artery ends on the nasal septum as the *posterior septal* branches, which anastomose with the ethmoidal arteries and the septal branch of the superior labial; one branch descends in a groove on the vomer to the incisive canal and anastomoses with the terminal ascending branch of the greater palatine artery.

THE TRIANGLES OF THE NECK (fig. 620)

The side of the neck presents a somewhat quadrilateral outline, limited, above, by the lower border of the body of the mandible, and a line drawn from the angle of the mandible to the mastoid process; below, by the upper border of the clavicle; in front, by the middle line of the neck; behind, by the anterior margin of the Trapezius. This space is subdivided by the Sternocleidomastoideus, which passes obliquely across the neck, from the sternum and clavicle below, to the mastoid process and occipital bone above. The area in front of this muscle is called the *anterior triangle* of the neck; that behind it, the *posterior triangle*.

ANTERIOR TRIANGLE OF THE NECK

The anterior triangle of the neck is bounded anteriorly by the middle line of the neck, posteriorly, by the anterior margin of the Sternocleidomastoideus;

FIG. 620.—The triangles of the neck.

its base, directed upwards, is formed by the lower border of the body of the mandible, and a line from the angle of the mandible to the mastoid process; its apex is below, at the sternum. This space is subdivided into four smaller triangles which are named the muscular, carotid, submaxillary, and

The muscular, or inferior carotid, triangle is bounded, in front, by the median line of the neck from the hyoid bone to the sternum; behind, by the anterior margin of the Sternocleidomastoideus; above, by the superior belly of the Omohyoideus. It is covered by the skin, superficial fascia, Platysma and deep fascia, ramifying in which are some of the branches of the cutaneous cervical and supraclavicular nerves. Beneath these superficial structures are the Sternohyoideus and Sternothyroideus, which, together with the anterior margin of the Sternocleidomastoideus, conceal the lower part of the carotid sheath and its contents. In front of the sheath are a few descending filaments from the ansa hypoglossi; behind the sheath are the inferior thyroid artery, the recurrent nerve, and the sympathetic trunk; and on its medial side, the oesophagus, the trachea, the thyroid gland, and the lower part of the larynx.

The carotid triangle is limited, behind, by the Sternocleidomastoideus; below, by the superior belly of the Omohyoideus; and above, by the Stylohyoideus and the posterior belly of the Digastricus. It is covered by the skin, superficial fascia, Platysma, and deep fascia, ramifying in which are branches of the facial and the cutaneous cervical nerves. Its floor is formed by parts of the Thyrohyoideus, Hyoglossus, and the Constrictores pharyngis medius and inferior. When this space is dissected it is seen to contain the upper part of the common carotid artery, which bifurcates opposite the superior border of the thyroid cartilage into the external and internal carotid arteries. These vessels are somewhat concealed from view by the anterior margin of the Sternocleidomastoideus, which overlies them. The external and internal carotid arteries lie side by side, the external being the more anterior. The following branches of the external carotid artery are also met with: the superior thyroid, running forwards and downwards; the lingual, directly forwards; the external maxillary, forwards and upwards; the occipital, backwards; and the ascending pharyngeal, directly upwards on the medial side of the internal carotid. The veins met with are the internal jugular, which lies on the lateral side of the common and external carotid arteries; and veins corresponding to the above-mentioned branches of the external carotid artery—viz. the superior thyroid, the lingual, common facial, ascending pharyngeal, and sometimes the occipital—all of which end in the internal jugular vein. The nerves are the following. In front of the sheath of the common carotid artery is the ramus descendens hypoglossi. The hypoglossal nerve crosses both the internal and external carotid arteries, curving round the origin of the occipital artery. Within the sheath, between the common carotid artery and the internal jugular vein, and behind both, is the vagus nerve; behind the sheath, the sympathetic trunk. The accessory nerve descends for a short distance on the lateral side of the vessels before it pierces the Sternocleidomastoideus; and on the medial side of the external carotid artery, just below the hyoid bone, may be seen the internal branch of the superior laryngeal nerve; and, still more inferiorly, the external branch of the same nerve. The upper portion of the larynx and lower portion of the pharynx are also found in the anterior part of this triangle.

The submaxillary, or digastric, triangle is bounded, above, by the lower border of the body of the mandible, and a line drawn from its angle to the mastoid process; below, by the posterior belly of the Digastricus and the Stylohyoideus; in front, by the anterior belly of the Digastricus. It is covered by the skin, superficial fascia, Platysma, and deep fascia, ramifying in which are branches of the facial and cutaneous cervical nerves. Its floor is formed by the Mylohyoideus, Hyoglossus, and Constrictor pharyngis superior. It is divided into an anterior and a posterior part by the stylomandibular ligament. The anterior part contains the submaxillary gland, superficial to which is the anterior facial vein, while imbedded in a groove on the posterior border of the gland is the external maxillary artery; beneath the gland, on the surface of the Mylohyoideus, are the submental artery and the mylohyoid artery and nerve. The posterior part of this triangle contains the external carotid artery, which ascends deeply in the substance of the parotid gland; in this triangle the external carotid artery is in front of, and superficial to, the internal carotid artery, and is crossed by the facial nerve; it gives off in its course the posterior auricular, superficial temporal, and internal maxillary

branches; more deeply are the internal carotid artery, the internal jugular vein, and the vagus nerve, which are separated from the external carotid artery by the Styloglossus, the Stylopharyngeus, and the glossopharyngeal nerve.

The **suprahyoid-triangle** is limited, behind, by the anterior belly of the Digastricus, in front, by the middle line of the neck from the mandible to the hyoid bone, and below, by the body of the hyoid bone; its floor is formed by the Mylohyoideus. It contains one or two lymph-glands and some small veins; the latter unite to form the anterior jugular vein.

POSTERIOR TRIANGLE OF THE NECK

The **posterior triangle** of the neck is bounded, in front, by the Sternocleidomastoideus; behind, by the anterior margin of the Trapezius; its base is formed by the middle third of the clavicle; its apex is at the occipital bone between the attachments of the Sternocleidomastoideus and the Trapezius. The triangle is crossed, about 2.5 cm. above the clavicle, by the inferior belly of the Omohyoideus, which divides the triangle into an occipital and a subclavian triangle.

The **occipital triangle**, the upper and larger division of the posterior triangle, is bounded in front by the Sternocleidomastoideus; behind, by the Trapezius; below, by the Omohyoideus. Its floor is formed from above downwards by the Splenius capitis, Levator scapulæ, and the Scaleni medius and posterior. It is covered by the skin, the superficial and deep fasciæ, and by the Platysma below. The accessory nerve pierces the Sternocleidomastoideus and is directed obliquely across the space to the under surface of the Trapezius; below, the supraclavicular nerves and the transverse cervical vessels and the upper part of the brachial plexus cross the space. A chain of lymph-glands is also found running along the posterior border of the Sternocleidomastoideus, from the mastoid process to the root of the neck.

The **subclavian triangle**, the lower and smaller division of the posterior triangle, is bounded, above, by the inferior belly of the Omohyoideus; below, by the clavicle; its base is formed by the lower part of the posterior border of the Sternocleidomastoideus. Its floor consists of the first rib and the first digitation of the Serratus anterior. The size of this triangle varies with the extent of attachment of the clavicular portions of the Sternocleidomastoideus and Trapezius, and also with the level at which the inferior belly of the Omohyoideus crosses the neck; this level is lowered when the arm is raised, and raised when the arm is depressed. The triangle is covered by the skin, the superficial and deep fasciæ, and the Platysma below. It is crossed by the supraclavicular nerves. Just above the level of the clavicle, the third portion of the subclavian artery curves lateralwards and downwards from the lateral margin of the Scalenus anterior, across the first rib, to the axilla. The subclavian vein lies behind the clavicle, and is not usually seen in this space; but in some cases it rises as high as the artery, and has even been seen to accompany that vessel behind the Scalenus anterior. The brachial plexus of nerves lies partly above and partly behind the artery, and in close contact with it. Passing transversely behind the clavicle are the transverse scapular vessels; and running in the same direction, but at a slightly higher level are the transverse cervical artery and vein. The external jugular vein descends behind the posterior border of the Sternocleidomastoideus, to terminate in the subclavian vein; it receives the transverse cervical and transverse scapular veins, which form a plexus in front of the third part of the subclavian artery, and occasionally it is joined by a small vein which crosses the clavicle from the cephalic vein. The small nerve to the Subclavius also crosses this triangle about its middle, and some lymph-glands are contained within the space.

INTERNAL CAROTID ARTERY

The internal carotid artery (fig. 621) supplies the greater part of the cerebral hemisphere, the eye and its appendages, and sends branches to the forehead and nose. It begins at the bifurcation of the common carotid artery,

FIG. 621.—The internal carotid and vertebral arteries. Right side.

ascends to the base of the skull, and enters the cranial cavity through the carotid canal of the temporal bone. It then runs forward through the cavernous sinus, lying in the carotid sulcus on the side of the body of the sphenoidal bone, and ends below the anterior perforated substance of the brain by dividing into the anterior and the middle cerebral arteries.

The internal carotid artery may be divided into four portions: cervical, petrous, cavernous, and cerebral.

Cervical Portion.—This portion of the internal carotid artery begins at the bifurcation of the common carotid, opposite the upper border of the thyroid cartilage and ascends in front of the transverse processes of the upper three cervical vertebrae to the lower end of the carotid canal in the petrous portion of the temporal bone. It is comparatively superficial at its commencement, where it is contained in the carotid triangle, and lies behind and lateral to the external carotid, overlapped by the Sternocleidomastoideus, and covered by the deep fascia, Platysma, and skin: it then passes beneath the parotid gland, being crossed by the hypoglossal nerve, the Digastricus and Stylohyoideus, and the occipital and posterior auricular arteries. Higher up, it is separated from the external carotid by the Styloglossus and Stylopharyngeus, the tip of the styloid process and the stylohyoid ligament, the glossopharyngeal nerve and the pharyngeal branch of the vagus. It is in relation behind, with the Longus capitis, the superior cervical ganglion of the sympathetic trunk, and the superior laryngeal nerve; laterally, with the internal jugular vein and vagus nerve, the nerve lying on a plane posterior to the artery; medially, with the internal maxillary, superior laryngeal nerve, and ascending pharyngeal artery. At the base of the skull the glossopharyngeal, vagus, accessory, and hypoglossal nerves lie between the artery and the internal jugular vein.

Petrous Portion.—When the internal carotid artery enters the canal in the petrous portion of the temporal bone, it first ascends a short distance, then curves forward and medialwards, and again ascends as it leaves the canal to enter the cranial cavity between the lingula and petrosal process of the sphenoidal bone. The artery lies at first in front of the cochlea and tympanic cavity; from the latter cavity it is separated by a thin, bony lamella, which is cribriform in the young subject and often partially absorbed in old age. Farther forwards it is separated from the nodular ganglion by a thin plate of bone, which forms the floor of the fossa for the ganglion and the roof of the horizontal portion of the carotid canal. Frequently this bony plate is more or less deficient, and then the ganglion is separated from the artery by fibrous membrane. The artery is surrounded by a number of small veins and the carotid plexus of nerves which is derived from the ascending branch of the superior cervical ganglion of the sympathetic trunk.

Cavernous Portion.—In this part of its course, the artery is situated between the layers of the dura mater forming the cavernous sinus (fig. 622), but covered by the lining membrane of the sinus. It at first ascends towards the posterior clinoid process, then passes forwards on the side of the body of the sphenoidal bone, and again curves upwards on the medial side of the anterior clinoid process, and perforates the dura mater, forming a root of the sinus; occasionally the anterior and middle clinoid processes form a bony ring round the artery. The cavernous portion of the artery is surrounded by the cavernous plexus of the sympathetic, and lateral to it are the oculomotor, trochlear, ophthalmic and abducent nerves (fig. 622).

Cerebral Portion.—After perforating the dura mater on the medial side of the anterior clinoid process, the internal carotid passes between the optic and oculomotor nerves to the anterior perforated substance at the medial extremity of the lateral cerebral fissure, where it gives off its terminal or cerebral branches.

Peculiarities.—The length of the internal carotid varies with the length of the neck, and with the point of bifurcation of the common carotid. It arises occasionally from the arch of the aorta, and then has been found medially to the external carotid, as far upwards as the larynx, where it crossed and this vessel to reach its usual position. The course of the artery, instead of being straight, may be very tortuous. A few instances are recorded in which this vessel was absent; in one of these the common carotid passed up the neck, and gave off the branches normally arising from the external carotid; the

FIG. 622 Oblique section through the right cavernous sinus.

cranial portion of the internal carotid was replaced by two branches of the internal maxillary, which entered the skull through the foramen rotundum and foramen ovale, and joined to form a single vessel.

Applied Anatomy.—The cervical part of the internal carotid is very rarely wounded. It is, however, sometimes injured by a stab or gunshot-wound in the neck, or even occasionally by a stab from within the mouth. Although the internal carotid lies about 2 cm. behind and lateral to the tonsil, instances have occurred in which the artery has been wounded during the operation of excision of the tonsil, and fatal hæmorrhage has supervened. The incision for ligature of the cervical portion of the internal carotid should be made along the anterior border of the Sternocleidomastoideus, from the angle of the mandible to the upper border of the thyroid cartilage. The superficial structures being divided, and the Sternocleidomastoideus defined and drawn backwards, the areolar tissue must be carefully separated and the posterior belly of the Digastricus and the hypoglossal nerve sought as guides to the vessel. The external carotid should be drawn medialwards and the Digastricus upwards, and the aneurysm needle passed from the lateral to the medial side of the vessel.

Obstruction of the internal carotid by embolism or thrombosis may give rise to symptoms of cerebral anæmia and softening if the collateral circulation is ill-developed. The patient suffers from giddiness, with failure of the mental powers; and convulsions, coma, or hemiplegia on the opposite side of the body, may be observed.

Branches.—No branches arise from the cervical portion of the internal carotid artery. Those from the other portions are :

From the petrous portion

1. Caroticotympanic.
2. Pterygoid.
3. Cavernous.
4. Hypophysial.

From the cavernous portion

5. Semilunar.
6. Anterior meningeal.
7. Ophthalmic.
8. Anterior cerebral.

From the cerebral portion

9. Middle cerebral.
10. Posterior communicating.
11. Chorioidal.

1. The **caroticotympanic branch** is very small; it enters the tympanic cavity through a foramen in the wall of the carotid canal, and anastomoses with the anterior tympanic branch of the internal maxillary, and with the stylomastoid artery.

2. A small, inconstant **pterygoid branch** passes into the pterygoid canal and anastomoses with a branch of the descending palatine artery.

3. The **cavernous branches** are numerous small vessels which supply the hypophysis, the semilunar ganglion, and the walls of the cavernous and inferior petrosal sinuses. Some of them anastomose with branches of the middle meningeal artery.

4. The **hypophysial branches** are one or two minute vessels which supply the hypophysis.

5. The **semilunar branches** are small vessels supplying the semilunar ganglion.

6. The **anterior meningeal branch** is a minute branch which passes over the small wing of the sphenoid to supply the dura mater of the anterior cranial fossa; it anastomoses with the meningeal branch from the posterior ethmoidal artery.

7. The **ophthalmic artery** (fig. 623) arises from the internal carotid, just as that vessel is emerging from the cavernous sinus on the medial side of the anterior clinoid process; it enters the orbital cavity through the optic foramen, below and laterally to the optic nerve. In the orbital cavity it runs for a short distance laterally to the optic nerve and medially to the Rectus lateralis and ciliary ganglion. It then crosses obliquely over the nerve to reach the medial wall of the orbit, and thence passes horizontally forwards, beneath the lower border of the Obliquus superior, and divides into two terminal branches, the *frontal* and the *dorsal nasal*. As the artery crosses the optic nerve it is accompanied by the nasociliary nerve, and is separated from the frontal nerve by the Rectus superior and Levator palpebræ superioris.

The branches of the ophthalmic artery are :—

Central artery of retina.

Lacrimal.

Muscular.

Short posterior ciliary.

Long posterior ciliary.

Anterior ciliary.

Supraorbital.

Posterior ethmoidal.

Anterior ethmoidal.

Anterior meningeal.

Medial palpebral.

Frontal.

Dorsal nasal.

The *central artery of the retina* is the first and one of the smallest branches of the ophthalmic artery. It runs for a short distance within the dural sheath of the optic nerve, and about 1.25 cm. behind the eyeball it pierces the under surface of the nerve, and runs forward in its centre to the retina. Its mode of distribution is described with the anatomy of the eye.

The *lacrimal artery* arises close to the optic foramen, and is one of the largest branches of the ophthalmic artery: sometimes it is given off before the ophthalmic artery enters the orbit; occasionally it is derived from one of the anterior branches of the middle meningeal artery. It accompanies the lacrimal nerve along the upper border of the Rectus lateralis, and supplies the lacrimal gland. Its terminal branches, escaping from the gland, are distributed to the eyelids and conjunctiva: of those supplying the eyelids, two are of considerable size and are named the *lateral palpebral arteries*; they run medialwards in the upper and lower lids respectively and anastomose with the medial

FIG. 623.—The ophthalmic artery and its branches.

palpebral arteries. The lacrimal artery gives off one or two *zygomatic branches*, one of which passes through the zygomaticotemporal foramen to the temporal fossa, and anastomoses with the deep temporal arteries; another appears on the cheek through the zygomaticofacial foramen and anastomoses with the transverse facial. A *recurrent meningeal branch* passes backwards through the lateral part of the superior orbital fissure to the dura mater, and anastomoses with a branch of the middle meningeal artery.

The *muscular branches* frequently spring from a common trunk. They consist of a superior and an inferior group, and most of them accompany the branches of the oculomotor nerve. The superior group, often wanting, supplies the Levator palpebrae superioris, Rectus superior, and Obliquus superior. The inferior group, more constantly present, is distributed to the Recti lateralis, medialis, and inferior, and the Obliquus inferior. This group gives off most of the anterior ciliary arteries. Additional muscular branches are derived from the lacrimal and supraorbital arteries, or from the trunk of the ophthalmic artery.

The *ciliary arteries* are divisible into three groups, long and short posterior, and anterior. The *long posterior ciliary arteries*, two in number, pierce the posterior part of the sclera a short distance from the entrance of the optic nerve, and run forwards, along either side of the eyeball, between the sclera and chorioid, to the ciliary muscles, where each divides into a superior and an inferior branch; these form, together with the anterior ciliary arteries, an arterial circle, the *circulus arteriosus major*, around the circumference of the iris; from the *circulus arteriosus major* numerous converging branches run in the

substance of the iris to its pupillary margin, where they form a second arterial circle, the *circulus arteriosus minor*. The *short posterior ciliary arteries*, from six to twelve in number, arise from the ophthalmic, or its branches; they pass forwards around the optic nerve to the posterior part of the eyeball, pierce the sclera around the entrance of the nerve, and supply the choroid coat and the ciliary processes. The *anterior ciliary arteries* are derived from the muscular branches of the ophthalmic artery; they run to the front of the eyeball in company with the tendons of the Recti, form a vascular zone beneath the conjunctiva, and then pierce the sclera a short distance from the sclero-corneal junction and end in the *circulus arteriosus major*.

The *supraorbital artery* leaves the ophthalmic artery as that vessel crosses the optic nerve. It ascends on the medial borders of the Rectus superior and Levator palpebræ superioris, and meeting the supraorbital nerve accompanies it between the periosteum and Levator palpebræ superioris to the supraorbital foramen; passing through this it divides into a superficial and a deep branch, which supply the skin, muscles, and pericranium of the forehead, anastomosing with the frontal, the frontal branch of the superficial temporal, and the artery of the opposite side. In the orbit it supplies twigs to the Rectus superior and the Levator palpebræ, and sends a branch across the pulley of the Obliquus superior, to the parts at the medial palpebral commissure. At the supraorbital foramen it frequently sends a branch to the diploë.

The *posterior ethmoidal artery* runs through the posterior ethmoidal canal, supplies the posterior ethmoidal cells, and, entering the cranium, gives off a meningeal branch to the dura mater, and nasal branches which descend into the nasal cavity through the lamina cribrosa of the ethmoidal bone, and anastomose with branches of the sphenopalatine artery.

The *anterior ethmoidal artery* accompanies the anterior ethmoidal nerve through the anterior ethmoidal canal, supplies the anterior and middle ethmoidal cells and frontal sinus, and, entering the cranium, gives off a meningeal branch to the dura mater, and nasal branches; the latter descend into the nasal cavity with the anterior ethmoidal nerve and, running along the groove on the inner surface of the nasal bone, supply twigs to the lateral wall and septum of the nose, and a terminal branch which appears on the dorsum of the nose between the nasal bone and the lateral cartilage.

The *anterior meningeal artery* is a small branch which passes to the middle cranial fossa through the superior orbital fissure and anastomoses with the middle and accessory meningeal arteries.

The *medial palpebral arteries*, two in number, superior and inferior, arise from the ophthalmic, opposite the pulley of the Obliquus superior, and run lateralwards in the eyelids near their free margins, forming a superior and an inferior arch, which lie between the Orbicularis oculi and the tarsi. The superior palpebral artery anastomoses with the supraorbital artery, and, at the lateral angle of the orbit, with the zygomatico-orbital branch of the temporal artery, and with the upper of the two lateral palpebral branches of the lacrimal artery; the inferior palpebral artery anastomoses at the lateral angle of the orbit with the lower of the two lateral palpebral branches of the lacrimal and with the transverse facial artery, and at the medial part of the eyelid with a twig from the angular artery. From this last anastomosis a branch passes to the nasolacrimal duct, ramifying in its mucous membrane, as far as the inferior meatus of the nasal cavity.

The *frontal artery*, one of the terminal branches of the ophthalmic, leaves the orbit at its medial angle with the supra-trochlear nerve, and, ascending on the forehead, supplies the skin, muscles, and pericranium, anastomosing with the supraorbital artery, and with the artery of the opposite side.

The *dorsal nasal artery*, the other terminal branch of the ophthalmic, emerges from the orbit above the medial palpebral ligament, and, after giving a twig to the upper part of the lacrimal sac, divides into two branches, one of which crosses the root of the nose, and anastomoses with the angular artery; the other runs along the dorsum of the nose, supplies its outer surface, and anastomoses with the artery of the opposite side, and with the lateral nasal branch of the external maxillary artery.

8. The *anterior cerebral artery* (figs. 624, 625, 626) arises from the internal carotid artery, at the medial end of the lateral cerebral fissure. It passes forwards and medialwards across the anterior perforated substance, above the optic nerve, to the commencement of the longitudinal fissure. Here it comes into close relationship with the opposite artery and is connected with it by a short transverse trunk named the anterior communicating artery. From this point, the two anterior cerebral arteries run side by side in the longitudinal cerebral fissure, curving round the genu of the corpus callosum, and running backwards along the upper surface of this structure to its posterior extremity, where they end by anastomosing with the posterior cerebral arteries.

The *anterior communicating artery* has an average length of about 4 mm. and connects the two anterior cerebral arteries across the commencement of the longitudinal fissure; in about 7 per cent. of cases it is double. It gives off a few anteromedial ganglionic branches.

In its course the anterior cerebral artery gives off the following branches :

Anteromedial ganglionic.
Inferior.

Anterior.
Middle.

Posterior.

The *anteromedial ganglionic branches* are a group of small arteries which arise from the commencement of the anterior cerebral artery ; they pierce the anterior perforated substance and lamina terminalis, and supply the rostrum of the corpus callosum, the septum pellucidum, and the head of the caudate nucleus. The *inferior branches*, two or three in number, are distributed to the orbital surface of

FIG. 624.—The arteries at the base of the brain.

the frontal lobe, where they supply the olfactory lobe, gyrus rectus, and medial orbital gyrus. The *anterior branches* supply a part of the superior frontal gyrus, and send twigs over the superomedial border of the cerebral hemisphere to the superior and middle frontal gyri and upper part of the anterior central gyrus. The *middle branches* supply the corpus callosum, the cingulate gyrus, the medial surface of the superior frontal gyrus, and the upper part of the anterior central gyrus. The *posterior branches* supply the præcuneus and adjacent lateral surface of the hemisphere.

9. The *middle cerebral artery* (figs. 624, 625), the largest branch of the internal carotid artery, runs at first lateralwards in the lateral cerebral fissure and then backwards and upwards on the surface of the insula, where it divides into branches which are distributed to the insula and to the lateral surface of the cerebral hemisphere.

The branches of this vessel are the

Anterolateral ganglionic.
Inferior lateral frontal.
Ascending frontal.

Ascending parietal.
Parietotemporal.
Temporal.

The *anterolateral ganglionic branches*, a group of small arteries which arise from the commencement of the middle cerebral artery, are arranged in two sets: one,

FIG. 625.—Lateral surface of cerebral hemisphere, showing the areas supplied by the cerebral arteries. In this and the next figure the areas supplied by the anterior cerebral artery are coloured *blue*; those by the middle cerebral artery, *pink*; and those by the posterior cerebral artery, *yellow*.

the *internal striate*, ascends through the inner segments of the lentiform nucleus, and supplies it, the caudate nucleus, and the internal capsule; the other, the *external striate*, ascends through the outer segment of the lentiform nucleus, and supplies the caudate nucleus and the thalamus. One artery of this group is larger than the rest, and of special importance, as being the artery in the brain most frequently ruptured; it has been termed by Charcot the '*artery of cerebral hæmorrhage*.' It ascends between the lentiform nucleus and the external capsule, and ends in the caudate nucleus. The *inferior lateral frontal* supplies the inferior frontal

FIG. 626.—Medial surface of cerebral hemisphere, showing the areas supplied by the cerebral arteries (see description of fig. 625).

gyrus (Broca's convolution) and the lateral part of the orbital surface of the frontal lobe. The *ascending frontal* supplies the anterior central gyrus. The *ascending parietal* is distributed to the posterior central gyrus and the lower part of the superior parietal lobule. The *parietotemporal* supplies the supramarginal and angular gyri, and the posterior parts of the superior and middle temporal gyri. The *temporal branches*, two or three in number, are distributed to the lateral surface of the temporal lobe.

10. The *posterior communicating artery* (fig. 624) runs backwards from the internal carotid above the oculomotor nerve, and anastomoses with the posterior

cerebral, a branch of the basilar artery. It is usually a small vessel, but is occasionally so large that the posterior cerebral may be considered as arising from the internal carotid rather than from the basilar. It is frequently larger on one side than on the other. From its posterior half are given off several small *posteromedial ganglionic branches*, which, with similar vessels from the posterior cerebral artery, pierce the posterior perforated substance and supply the medial surfaces of the thalami and the walls of the third ventricle.

11. The *anterior chorioidal artery*, a small but constant branch, arises from the internal carotid, near the posterior communicating artery. Passing backwards and lateralwards between the uncus and the cerebral peduncle, it enters the inferior horn of the lateral ventricle through the chorioidal fissure and ends in the chorioid plexus. It is distributed to the hippocampus, fimbria, tela chorioides of the third ventricle, and chorioid plexus.

Arterial circle of Willis.—A considerable part of the brain is supplied by the two vertebral arteries (p. 606), and a remarkable anastomosis, named the *arterial circle of Willis*, exists between these vessels and the two internal carotid arteries. This circle is situated in the subarachnoid space at the base of the brain, and encloses the optic chiasma and the structures in the interpeduncular fossa (p. 804). It is formed as follows: in front, the two anterior cerebral arteries are joined to one another by the anterior communicating artery; behind, the basilar artery (formed by the union of the vertebral arteries) divides into the two posterior cerebral arteries, each of which is joined to the internal carotid artery of the same side by the posterior communicating artery (fig. 627).

FIG. 627.—Diagram of the arteries at the base of the brain.

THE ARTERIES OF THE BRAIN

The mode of distribution of the vessels of the brain has an important bearing upon a considerable number of the pathological lesions which may occur in this part of the nervous system.

The arteries which supply the brain give origin to two different systems of vessels. One of these is named the *ganglionic system*, and its vessels supply the thalami and corpora striata; the other is the *cortical system*, and its vessels ramify in the pia mater and supply the cortex and subjacent brain-substance. These two systems are independent of one another and do not communicate at any point of their peripheral distribution, and there is between the parts supplied by the two systems a borderland of diminished nutritive activity where, it is said, softening of the brain is especially liable to occur.

The ganglionic system.—All the vessels of this system are given off from the circle of Willis, described above, or from the vessels close to it. They form six principal groups: (i) an *anteromedial group*, derived from the anterior cerebral and anterior communicating arteries; (ii) a *posteromedial group*, from the posterior cerebral and posterior communicating arteries; (iii and iv) right and left *anterolateral groups*, from the middle cerebral arteries; and (v and vi) right and left *posterolateral groups*, from the posterior cerebral arteries after they have wound round the cerebral peduncles. The vessels of this system are larger than those of the cortical system, and are what Cohnheim designated *terminal arteries*—that is to say, vessels which from their origin to their termination neither supply nor receive any anastomotic branch, so that, through any one of the vessels only a limited area of the thalamus or corpus striatum can be injected.

The cortical system.—The vessels of this system are the terminal branches of the anterior, middle, and posterior cerebral arteries. They divide in the substance of the pia mater, give off branches which penetrate the brain-cortex perpendicularly, and are divisible into two classes, long and short. The *long*, or *medullary arteries*, pass through the grey substance and penetrate the subjacent white substance to the depth of 3 or 4 cm., without intercommunicating otherwise than by very fine capillaries, and thus constitute so many independent small systems. The *short vessels* are confined to the cortex, where they form with the long vessels a compact network in the middle zone of the grey substance, the outer and inner zones being sparingly supplied with blood. The vessels of the cortical system are not so strictly 'terminal' as those of the ganglionic system, but they approach this type very closely, so that injection of one area from the vessel of another area, though possible, is difficult, and only effected through vessels of small calibre; obstruction of one of these vessels may therefore produce softening in a limited area of the brain cortex.

ARTERIES OF THE UPPER EXTREMITY

The artery which supplies the upper extremity runs as a single trunk as far as the elbow; but is differently named, according to the regions through which it passes. From its origin to the outer border of the first rib it is termed *subclavian*; from the outer border of the first rib to the lower border of the tendon of the Teres major, it is named *axillary*; and from the lower border of the Teres major to a point opposite the neck of the radius it is termed *brachial*.

SUBCLAVIAN ARTERIES (fig. 628)

The right subclavian artery arises from the innominate artery, the left from the arch of the aorta. The vessels, therefore, in the first parts of their courses, differ in length, direction, and relation with neighbouring structures.

To facilitate the description, each subclavian artery is divided into three parts; the first extends from the origin of the vessel to the medial border of the Scalenus anterior, the second lies behind this muscle, and the third runs from the lateral margin of the muscle to the outer border of the first rib, where it becomes the axillary artery. The first portions of the two vessels require separate descriptions; their second and third parts are almost alike.

FIRST PART OF THE RIGHT SUBCLAVIAN ARTERY (figs. 621, 628)

The first part of the right subclavian artery arises from the innominate artery, behind the upper part of the right sternoclavicular articulation, and passes upwards and lateralwards to the medial margin of the Scalenus anterior. It ascends, on an average, about 2 cm. above the clavicle, but the height it reaches varies considerably in different cases.

Relations.—It is covered, *in front*, by the skin, superficial fascia, Platysma, deep fascia, the clavicular origin of the Sternocleidomastoideus, the Sternohyoideus, and Sternothyroideus. It is crossed by the internal jugular and vertebral veins, by the vagus nerve and the cardiac branches of the vagus and sympathetic; the subclavian loop of the sympathetic trunk encircles the vessel. The anterior jugular vein is directed lateralwards in front of the artery, but is separated from it by the Sternohyoideus and Sternothyroideus. *Below and behind* the artery are the pleura and the apex of the lung; *behind* is the sympathetic trunk, the Longus colli and the first thoracic vertebra. The right recurrent nerve winds round the lower and posterior part of the vessel.

FIRST PART OF THE LEFT SUBCLAVIAN ARTERY (fig. 613)

The first part of the left subclavian artery arises from the arch of the aorta, behind the left common carotid, and at the level of the upper border of the fourth thoracic vertebra; it ascends in the superior mediastinal cavity to the root of the neck and then arches lateralwards to the medial border of the Scalenus anterior.

Relations.—It is in relation, *in front*, with the vagus, cardiac, and phrenic nerves, the left common carotid artery, the left internal jugular and vertebral veins

and the beginning of the left innominate vein, and is covered by the Sternothyroideus, Sternohyoideus, and Sternocleidomastoideus; *behind*, it is in relation with the œsophagus, thoracic duct, left recurrent nerve, inferior cervical ganglion of the sympathetic trunk, and Longus colli; higher up, however, the œsophagus and thoracic duct lie to its right side, the latter ultimately arching over the vessel to

FIG. 628.—Superficial dissection of the right side of the neck, showing the carotid and subclavian arteries.

join the angle of union between the subclavian and internal jugular veins. *Medially* to it are the œsophagus, trachea, thoracic duct, and left recurrent nerve; *laterally* to it, the left pleura and lung.

SECOND AND THIRD PARTS OF THE SUBCLAVIAN ARTERY (fig. 628)

The **second portion** of the subclavian artery lies behind the Scalenus anterior; it is very short, and forms the highest part of the arch described by the vessel.

Relations.—It is covered, *in front*, by the skin, superficial fascia, Platysma, deep cervical fascia, Sternocleidomastoideus, and Scalenus anterior. On the right side of the neck the phrenic nerve is separated from the second part of the artery by the Scalenus anterior, while on the left side it crosses the first part of the artery close to the medial edge of the muscle. *Behind* and *below* the vessel are the pleura and lung; *above*, the brachial plexus of nerves. The subclavian vein lies below and in front of the artery, separated from it by the Scalenus anterior.

The third portion of the subclavian artery runs downwards and laterally from the lateral margin of the Scalenus anterior to the outer border of the first rib, where it becomes the axillary artery. This is the most superficial portion of the vessel, and is contained in the subclavian triangle (p. 593).

Relations.—*In front* of it are the skin, the superficial fascia, the Platysma, the supraclavicular nerves, and the deep cervical fascia. The external jugular vein crosses its medial part and receives the transverse scapular, transverse cervical, and anterior jugular veins, which frequently form a plexus in front of the artery. Behind the veins, the nerve to the Subclavius descends in front of the artery. The terminal part of the artery lies behind the clavicle and the Subclavius and is crossed by the transverse scapular vessels. The subclavian vein is in front of, and at a slightly lower level than, the artery. The lowest trunk of the brachial plexus lies *behind* the artery and intervenes between it and the Scalenus medius. *Above*, and to its *lateral side*, are the upper trunks of the brachial plexus, and the Omo-hyoideus. *Below*, it rests on the upper surface of the first rib.

Peculiarities.—The subclavian arteries vary in their origin, their course, and the height to which they rise in the neck.

The right subclavian sometimes arises from the innominate above the level of the sternoclavicular articulation; occasionally below the level of that joint. It may arise as a separate trunk from the arch of the aorta and may then be either its first, second, third, or last branch; in the majority of cases it is the first or last. When it is the first branch, it occupies the ordinary position of the innominate artery; when the second or third, it passes behind the right carotid; and when the last it arises from the left extremity of the arch, and ascends obliquely toward the right side, usually behind the trachea, oesophagus, and right carotid, sometimes between the oesophagus and trachea, to the upper border of the first rib, whence it follows its ordinary course. Occasionally the artery perforates the Scalenus anterior, more rarely it passes in front of that muscle. Sometimes the subclavian vein passes with the artery behind the Scalenus anterior. The artery may ascend as high as 4 cm. above the clavicle or may only reach the level of the upper border of the bone.

The left subclavian is occasionally joined at its origin with the left carotid. It is more deeply placed than the right subclavian in the first part of its course, and, as a rule, does not reach quite as high a level in the neck.

The posterior border of the Sternocleidomastoideus corresponds closely to the lateral border of the Scalenus anterior, so that the third portion of the artery, the part most accessible for operation, lies immediately lateral to the posterior border of the Sternocleidomastoideus.

Applied Anatomy.—An aneurysm may form on any part of the subclavian artery, except the intrathoracic portion of the left vessel, which is said never to be the seat of aneurysm. The most common site is the third portion (especially on the right side) on account of the greater exposure to injury and the greater amount of use of the right upper extremity. In this situation it may cause pressure on the brachial plexus, producing pain and numbness in the arm and fingers, with loss of power or paralysis of the muscles of these parts. Edema of the arm may result from pressure on the subclavian vein. The external jugular vein may become distended and varicose. The treatment is unsatisfactory, since proximal ligature cannot be undertaken with much chance of success. If constitutional treatment and direct pressure on the aneurysmal sac fail, the best treatment is excision of the sac, if it be small. In aneurysms of the first portion of this artery there is edema of the head and face, with lividity, congestion of the brain, and semiconsciousness from pressure on the internal jugular vein; and spasm of the Diaphragm from pressure on the phrenic nerve. The collateral circulation is so good that blocking of the subclavian artery by embolism or thrombosis often fails to give rise to any striking signs or symptoms, beyond occasional pains in the neck and shoulder and some degree of weakness and wasting in the muscles of the arm.

Compression of the subclavian artery may be required to control hemorrhage, and can be effectually applied in one situation only, viz. where the artery passes across the upper surface of the first rib. In order to compress the vessel in this situation, the shoulder should be depressed, and the surgeon grasping the side of the neck should press with his thumb in the angle formed by the posterior border of the Sternocleidomastoideus with the upper border of the clavicle, downwards, backwards, and medially against

SUBCLAVIAN ARTERY

the rib; if from any cause the shoulder cannot be sufficiently depressed, pressure may be made from before backwards, so as to compress the artery against the *Scalenus medius* and transverse process of the seventh cervical vertebra. In appropriate cases, a preliminary incision may be made through the cervical fascia, and the finger may be pressed down directly upon the artery.

In cases of through-and-through gunshot wounds about the clavicle the formation of an arteriovenous aneurysm, or direct communication between the subclavian artery and some neighbouring vein, is not rare. This enables arterial blood at high pressure to escape into the vein; the vein is distended thereby, with the production of a pulsatile swelling that can be felt above or below the clavicle. In addition a thrill can be felt and a loud rushing murmur can be heard in the neighbourhood of the swelling; both thrill and murmur are continuous, but more forcible during cardiac systole. Not infrequently these arteriovenous aneurysms call for relief by operation.

Ligature of the subclavian artery may be required in cases of wounds, or of aneurysm in the axilla, or in cases of aneurysm on the cardiac side of the point of ligature. The vessel is also ligatured as a preliminary measure to the complete interscapulothoracic amputation of the upper extremity, in which case the transverse scapular and transverse cervical arteries may, if found, be ligatured at the same time, making the 'fore-quarter' amputation an almost bloodless procedure.

The third part of the artery is that which is most favourable for an operation, on account of its being comparatively superficial and most remote from the origin of the large branches. In those cases where the clavicle is not displaced, this operation may be performed with comparative facility; but where the clavicle is pushed up by a large aneurysmal tumour in the axilla, the artery lies at a great depth from the surface, and this materially increases the difficulty. Under these circumstances, it becomes a matter of importance to consider the height to which this vessel reaches above the bone. In ordinary cases, its arch is about 1.25 cm. above the clavicle, occasionally as high as 4 cm., and sometimes so low as to be on a level with its upper border. If the clavicle be displaced, these variations will necessarily make the operation more or less difficult, according as the vessel is less or more accessible.

The procedure in the operation of tying the third portion of the subclavian artery is as follows: The patient being placed on a table in the supine position, with the head drawn over to the opposite side, and the shoulder depressed as much as possible, the skin should be pulled downwards over the clavicle, and an incision made through it, upon that bone, from the anterior border of the *Trapezius* to the posterior border of the *Sternocleidomastoideus*. The object in drawing the skin down is to avoid any risk of wounding the external jugular vein, which perforates the fascia above the clavicle, and cannot be drawn downwards with the skin. The soft parts are allowed to glide up, and the cervical fascia is divided; if the interval between the *Trapezius* and *Sternocleidomastoideus* be insufficient, a portion of one or both may be divided. The external jugular vein will now be seen towards the medial side of the wound; this and the transverse scapular and transverse cervical veins which extend to it should be held aside. If any large vein be at all in the way and exposed to injury, it should be tied in two places and divided. The transverse scapular artery should be avoided, and the *Omo-hyoideus* held aside if necessary. In the space beneath this muscle a deep layer of fascia and some connective tissue are divided, the lateral margin of the *Scalenus anterior* is felt for, and the finger being guided by it to the first rib, the pulsation of the subclavian artery will be felt as it passes over the rib. The sheath of the vessels having been opened, the aneurysm needle may then be passed around the artery from above downwards and medialwards so as to avoid including any of the branches of the brachial plexus, which in operations on the cadaver are not uncommonly mistaken for the vessel. If the clavicle be so raised by the tumour that the application of the ligature cannot be effected in this situation, the artery may be tied above the first rib, or even behind the *Scalenus anterior*.

The second part of the subclavian artery, the portion which rises highest in the neck, has been considered favourable for the application of the ligature when it is difficult to tie the artery in the third part of its course. There are, however, many objections to the operation in this situation. It is necessary to divide the *Scalenus anterior*, upon which lies the phrenic nerve, and at the medial side of which is situated the internal jugular vein; and a wound of either of these structures might lead to the most dangerous consequences. Again, the artery is in contact, below, with the pleura, which must also be avoided; and, lastly, the proximity of so many of its large branches arising medially to this point is a further objection to the operation. In cases, however, where the sac of an axillary aneurysm encroaches on the neck, it may be necessary to divide the lateral half or two-thirds of the *Scalenus anterior*, so as to place the ligature on the vessel at a greater distance from the sac. The operation is performed exactly in the same way as a ligature of the third portion, until the *Scalenus anterior* is exposed, when it is to be divided on a director (never to a greater extent than its lateral two-thirds), and it immediately retracts. This is therefore merely an extension of the operation for ligature of the third portion of the vessel.

In those cases of aneurysm of the axillary or subclavian artery which encroach upon the lateral portion of the *Scalenus anterior* to such an extent that a ligature cannot be applied in that situation, it may be deemed advisable, as a last resource, to tie the first

portion of the subclavian artery. On the left side, this operation is almost impracticable; the great depth of the artery from the surface, its intimate relation with the pleura, and its close proximity to the thoracic duct and to so many important veins and nerves, present a series of difficulties which it is next to impossible to overcome. On the right side, the operation is practicable, the main difficulty being the smallness of the interval which usually exists between the commencement of the vessel and the origin of the nearest branch. The operation is essentially similar to that described on p. 575 for ligature of the innominate artery. The exact position of the vagus, recurrent, and phrenic nerves and the sympathetic trunk should be borne in mind, and the ligature should be applied near the origin of the vertebral, in order to afford as much room as possible for the formation of a coagulum between the ligature and the origin of the vessel. It should be remembered that the right subclavian artery is occasionally deeply placed in the first part of its course, when it arises from the left side of the aortic arch, and passes in such cases behind the oesophagus, or between it and the trachea.

Collateral Circulation.—After ligature of the third part of the subclavian artery, the collateral circulation is established mainly by three sets of vessels, thus described in a dissection:

1. A posterior set, consisting of the transverse scapular artery and the descending ramus of the transverse cervical branch of the subclavian, anastomosing with the subscapular from the axillary.

2. A medial set, produced by the connexion of the internal mammary on the one hand, with the arteria intercostalis suprema and the lateral thoracic and subscapular arteries on the other.

3. A middle or axillary set, consisting of a number of small vessels derived from branches of the subclavian and, passing through the axilla, terminating either in the axillary artery, or some of its branches. This last set presented most conspicuously the peculiar character of newly formed or, rather, dilated arteries, being excessively tortuous, and forming a complete plexus.

The chief agent in the restoration of the axillary artery below the aneurysm was the subscapular artery, which communicated freely with the internal mammary, transverse scapular, and descending ramus of the transverse cervical arteries of the subclavian, from all of which it received so great an influx of blood as to dilate it to three times its natural size.*

When a ligature is applied to the first part of the subclavian artery, the collateral circulation is carried on by the following anastomoses: 1, between the superior and inferior thyroids; 2, the two vertebrals; 3, the internal mammary with the inferior epigastric and the aortic intercostals; 4, the costocervical with the aortic intercostals; 5, the a. profunda cervicalis with the descending branch of the occipital; 6, the scapular branches of the thyrocervical trunk with the branches of the axillary; and 7, the thoracic branches of the axillary with the aortic intercostals.

Branches.—The branches of the subclavian artery are:

Vertebral.

Thyrocervical.

Internal mammary.

Costocervical.

On the left side of the neck all four branches generally arise from the first portion of the artery; on the right side the costocervical trunk usually springs from the second portion. On both sides, the first three branches originate close together at the medial border of the Scalenus anterior.

1. The vertebral artery (fig. 621) arises from the upper and posterior part of the first portion of the subclavian artery. It ascends through the foramina in the transverse processes of the upper six cervical vertebrae,† winds behind the superior articular process of the atlas, enters the skull through the foramen magnum, and, at the lower border of the pons, unites with the vessel of the opposite side to form the basilar artery.

Relations.—The vertebral artery may be divided into four parts. The *first part* runs upwards and backwards between the Longus colli and the Scalenus anterior. In front of it are the internal jugular and vertebral veins, and it is crossed by the inferior thyroid artery; the left vertebral artery is crossed by the thoracic duct also. Behind it are the transverse process of the seventh cervical vertebra, the sympathetic trunk and its inferior cervical ganglion. The *second part* ascends through the foramina transversaria of the upper six cervical vertebrae, and is surrounded by a plexus of nerves derived from the inferior cervical sympathetic ganglion, and by a plexus of veins which unite to form the vertebral vein at the

* *Guy's Hospital Reports*, vol. i. 1836. Case of axillary aneurysm, in which Astley Cooper had tied the subclavian artery at the lateral edge of the Scalenus anterior, twelve years previously.

† The vertebral artery sometimes enters the foramen in the transverse process of the fifth vertebra, and has been seen entering that of the seventh vertebra.

lower part of the neck. It lies in front of the trunks of the cervical nerves, and runs an almost vertical course as far as the transverse process of the epistropheus, through which it runs upwards and lateralwards to the foramen transversarium of the atlas. The *third part* issues from the latter foramen on the medial side of the Rectus capitis lateralis, and curves backwards behind the superior articular process of the atlas, the anterior ramus of the first cervical nerve being on its medial side; it then lies in the groove on the upper surface of the posterior arch of the atlas, and enters the vertebral canal by passing beneath the posterior atlanto-occipital membrane. This part of the artery is covered by the Semispinalis capitis and is contained in the *suboccipital triangle*, (which is bounded by the Rectus capitis posterior major, the Obliquus superior, and the Obliquus inferior. The posterior division of the first cervical nerve lies between the artery and the posterior arch of the atlas.) The *fourth part* pierces the dura mater, ascends in front of the roots of the hypoglossal nerve, and inclines medialwards to the front of the medulla oblongata, where, at the lower border of the pons, it unites with the vessel of the opposite side to form the basilar artery.

The branches of the vertebral artery may be divided into two sets—those given off in the neck, and those within the cranium.

Cervical branches.

Spinal.
Muscular.

Cranial branches.

Meningeal.
Posterior spinal.
Anterior spinal.
Posterior inferior cerebellar.
Medullary.

Spinal branches enter the vertebral canal through the intervertebral foramina, and each divides into two branches. Of these, one passes along the roots of the nerves to supply the medulla spinalis and its membranes, anastomosing with the other arteries of the medulla spinalis; the other divides into an ascending and a descending branch, which unite with similar branches from the arteries above and below, so that two lateral anastomotic chains are formed on the posterior surfaces of the bodies of the vertebræ, near the attachment of the pedicles. From these anastomotic chains branches are supplied to the periosteum and the bodies of the vertebræ, and others communicate with similar branches from the opposite side; from these communications small twigs arise which join similar branches above and below, to form a central anastomotic chain on the posterior surfaces of the bodies of the vertebræ.

Muscular branches arise from the vertebral artery as it curves round the superior articular process of the atlas. They supply the deep muscles of the neck and anastomose with the occipital artery, and the ascending and deep cervical arteries.

One or two **meningeal branches** spring from the vertebral opposite the foramen magnum, ramify between the bone and dura mater in the cerebellar fossa, and supply the falx cerebelli.

The **posterior spinal artery** arises at the side of the medulla oblongata; it passes backwards, and then descends in front of the posterior roots of the spinal nerves, and is reinforced by a succession of small branches, which enter the vertebral canal through the intervertebral foramina; by means of these it is continued to the lower part of the medulla spinalis, and to the cauda equina. Branches from the posterior spinal arteries form a free anastomosis round the posterior roots of the spinal nerves, and communicate with the vessels of the opposite side. Near its origin each posterior spinal artery gives off an ascending branch, which ends at the side of the fourth ventricle.

The **anterior spinal artery** is a small branch, which arises near the termination of the vertebral; it descends in front of the medulla oblongata and unites with its fellow of the opposite side at the level of the foramen magnum. The single trunk, thus formed, descends on the front of the medulla spinalis, and is reinforced by a succession of small branches which enter the vertebral canal through the intervertebral foramina; these branches are derived from the vertebral, and from the ascending cervical of the inferior thyroid in the neck; from the intercostals in the thorax, and from the lumbar, ilio-lumbar, and lateral sacral arteries in the abdomen and pelvis. They unite, by means of ascending and descending branches, to form a single anterior median artery, which extends as far as the lower part of the medulla spinalis, and is continued as a slender twig on the filum terminale.

This vessel is placed in the pia mater along the anterior median fissure; it supplies that membrane, and the substance of the medulla spinalis, and sends off branches at its lower part to be distributed to the cauda equina.

The **posterior inferior cerebellar artery** (fig. 624), the largest branch of the vertebral, winds backwards round the upper part of the medulla oblongata, passing between the roots of the vagus and accessory nerves, over the restiform body to the under surface of the cerebellum, where it divides into a medial and a lateral branch. The medial branch runs backwards to the notch between the hemispheres of the cerebellum, while the lateral supplies the under surface of the hemisphere, as far as its lateral border, where it anastomoses with the anterior inferior cerebellar and the superior cerebellar branches of the basilar artery. Branches from this artery supply the chorioid plexus of the fourth ventricle.

The **medullary arteries** are several minute vessels which spring from the vertebral and its branches, and are distributed to the medulla oblongata.

The **basilar artery** (fig. 624), so named from its position at the base of the skull, is formed by the junction of the two vertebral arteries; it extends from the lower to the upper border of the pons, lying in a median groove, under cover of the arachnoid. It is placed between the two abducent nerves at the lower border of the pons, and between the two oculomotor nerves at the upper border, where it ends by dividing into the two posterior cerebral arteries.

Its branches, on either side, are the following:

Pontine.	Anterior inferior cerebellar.
Internal auditory.	Superior cerebellar.
	Posterior cerebral.

The **pontine branches** are a number of small vessels which come off at right angles from either side of the basilar artery, and supply the pons and adjacent parts of the brain.

The **internal auditory artery**, a long slender branch, arises from near the middle of the basilar artery; it accompanies the acoustic nerve through the internal acoustic meatus and is distributed to the internal ear.

The **anterior inferior cerebellar artery** passes backwards to the anterior part of the under surface of the cerebellum, and anastomoses with the posterior inferior cerebellar branch of the vertebral artery.

The **superior cerebellar artery** arises near the termination of the basilar. It passes lateralwards immediately below the oculomotor nerve which separates it from the posterior cerebral artery, winds round the cerebral peduncle close to the trochlear nerve, and, arriving at the upper surface of the cerebellum, divides into branches which ramify in the pia mater and anastomose with those of inferior cerebellar arteries. Several branches are given to the pineal body, the anterior medullary velum, and the tela chorioides of the third ventricle.

The **posterior cerebral artery** (figs. 624, 625, 626) is larger than the superior cerebellar artery, from which it is separated near its origin by the oculomotor nerve, and on the side of the mesencephalon by the trochlear nerve. Passing lateralwards, parallel to the superior cerebellar artery, and receiving the posterior communicating branch from the internal carotid, it winds round the cerebral peduncle, and reaches the tentorial surface of the cerebrum, where it breaks up into branches for the supply of the temporal and occipital lobes.

The branches of the posterior cerebral artery are divided into two sets, ganglionic and cortical:

Ganglionic	Posteromedial.	Cortical	Anterior temporal.
	Posterior chorioid.		Posterior temporal.
	Posterolateral.		Calcarine.
			Parieto-occipital.

Ganglionic.—The **posteromedial ganglionic branches** (fig. 627) are several small arteries which arise at the commencement of the posterior cerebral artery, along with similar branches from the posterior communicating, pierce the posterior perforated substance, and supply the medial surfaces of the thalami and the walls of the third ventricle. The **posterior chorioid branches** run forwards beneath the splenium of the corpus callosum and supply the tela chorioides of the third ventricle and end in the chorioid plexus of the lateral ventricle. The **posterolateral ganglionic branches** are small arteries which arise from the posterior cerebral artery.

after it has turned round the cerebral peduncle ; they supply a considerable portion of the thalamus.

Cortical.—The cortical branches are : the *anterior temporal*, distributed to the uncus and the anterior part of the fusiform gyrus ; the *posterior temporal*, to the fusiform and the inferior temporal gyri ; the *calcarine*, to the cuneus, gyrus lingualis, and the posterior part of the lateral surface of the occipital lobe ; and the *parieto-occipital*, to the cuneus and the præcuneus.

The internal mammary artery arises from the under surface of the first portion of the subclavian artery, opposite the thyrocervical trunk. It descends behind the cartilages of the upper six ribs at a distance of about 1.25 cm. from the lateral border of the sternum, and at the level of the sixth intercostal space divides into the *musculophrenic* and *superior epigastric* arteries.

Relations.—It runs at first downwards, forwards, and medialwards behind the sternal end of the clavicle, the internal jugular and innominate veins, and the first costal cartilage. As the artery enters the thorax, the phrenic nerve crosses from its lateral to its medial side. Below the first costal cartilage it descends almost vertically to its point of bifurcation. It is covered in front by the Pectoralis major, the cartilages of the upper six ribs and the intervening Intercostales interni and anterior intercostal membranes, and is crossed by the terminal portions of the upper six intercostal nerves. It is separated from the pleura, as far as the second or third costal cartilage, by a strong layer of fascia ; below this level, by the Transversus thoracis muscle. It is accompanied by a chain of lymph-glands and a pair of veins : the veins unite above to form a single vessel, which runs medially to the artery and ends in the corresponding innominate vein.

The branches of the internal mammary artery are :

Pericardiophrenic.
Anterior mediastinal.
Pericardial.

Sternal.
Intercostal.
Perforating.)

Musculophrenic.
Superior epigastric.

The pericardiophrenic artery (a. comes nervi phrenici) is a long slender branch which accompanies the phrenic nerve, between the pleura and pericardium, to the Diaphragm ; it gives branches to the pleura, pericardium and Diaphragm, and anastomoses with the musculophrenic and inferior phrenic arteries.

The anterior mediastinal arteries are small vessels, distributed to the areolar tissue and lymph-glands in the anterior mediastinal cavity, and to the remains of the thymus.

The pericardial branches supply the upper part of the anterior surface of the pericardium.

The sternal branches are distributed to the Transversus thoracis muscle, and to the posterior surface of the sternum.

The anterior mediastinal, pericardial, and sternal branches, together with some twigs from the pericardiophrenic, anastomose with branches from the intercostal and bronchial arteries, and form a *subpleural mediastinal plexus*.

The intercostal branches supply the upper five or six intercostal spaces. Two in number in each space, they pass lateralwards, one lying near the lower margin of the rib above, and the other near the upper margin of the rib below, and anastomose with the intercostal arteries from the aorta. They are at first situated between the pleura and the Intercostales interni, and then between the Intercostales interni and externi. They supply the Intercostales and send branches through the Intercostales externi to the Pectorales and the mamma.

The perforating branches emerge through the upper five or six intercostal spaces. They pierce the Pectoralis major, and curving lateralwards, supply that muscle and the skin. Those of the second, third, and fourth spaces give branches to the mamma, and during lactation are of large size.

The musculophrenic artery is directed obliquely downwards and lateralwards, behind the cartilages of the false ribs ; it perforates the Diaphragm at the eighth or ninth costal cartilage, and ends, considerably reduced in size, opposite the last intercostal space. It gives off intercostal branches to the seventh, eighth, and ninth intercostal spaces ; these diminish in size as the spaces decrease in length, and are distributed in a manner similar to the intercostals from the internal mammary. The musculophrenic also gives branches to the lower part of the pericardium, the Diaphragm, and the abdominal muscles.

The superior epigastric artery descends through the interval between the costal and xiphoid origins of the Diaphragm, and enters the sheath of the Rectus abdominis, at first lying behind the muscle, and then perforating and supplying it, and anastomosing with the inferior epigastric artery from the external iliac. Branches

perforate the sheath of the Rectus, and supply the muscles and skin of the abdomen, and a small branch passes in front of the xiphoid process and anastomoses with the artery of the opposite side. The superior epigastric artery also gives some twigs to the Diaphragm, while from the artery of the right side small branches extend into the falciform ligament of the liver and anastomose with the hepatic artery.

Applied Anatomy.—The internal mammary artery is liable to be wounded in stabs of the chest-wall and in the operation of paracentesis pericardii (p. 553). It is most easily reached by a transverse incision in the second intercostal space.

3. The **thyrocervical trunk** (thyreoid axis) (fig. 628), a short thick trunk, arises from the front of the first portion of the subclavian artery, close to the medial border of the Scalenus anterior, and divides almost immediately into three branches, the *inferior thyreoid*, *transverse scapular*, and *transverse cervical*.

The **inferior thyreoid artery** runs upwards in front of the vertebral artery and Longus colli; it then turns medialwards behind the carotid sheath and its contents, and also behind the sympathetic trunk, the middle cervical ganglion of which rests upon the vessel; it finally descends to the lower border of the lateral lobe of the thyreoid gland. The recurrent nerve runs upwards generally behind, but occasionally in front of, the artery.

The branches of the inferior thyreoid are :

Muscular.	Inferior laryngeal.	Œsophageal.
Ascending cervical.	Tracheal.	Glandular.

The **muscular branches** supply the depressors of the hyoid bone, and the Longus colli, Scalenus anterior, and Constrictor pharyngis inferior.

The **ascending cervical artery** is a small branch which arises from the inferior thyreoid as that vessel is passing behind the carotid sheath; it ascends on the anterior tubercles of the transverse processes of the cervical vertebræ in the interval between the Scalenus anterior and Longus capitis. It gives twigs to the muscles of the neck, and sends one or two spinal branches into the vertebral canal through the intervertebral foramina to be distributed to the medulla spinalis and its membranes, and to the bodies of the vertebræ, in the same manner as the spinal branches from the vertebral artery. It anastomoses with the vertebral, ascending pharyngeal and occipital arteries.

The **inferior laryngeal artery** ascends upon the trachea in company with the recurrent nerve; it enters the larynx under the lower border of the Constrictor pharyngis inferior, and supplies its muscles and mucous membrane, anastomosing with the artery from the opposite side, and with the superior laryngeal branch of the superior thyreoid artery.

The **tracheal branches** are distributed to the trachea, and anastomose below with the bronchial arteries.

The **œsophageal branches** supply the œsophagus, and anastomose with the œsophageal branches of the thoracic aorta.

The **glandular branches** consist of an inferior and an ascending branch; they supply the posterior and inferior parts of the thyreoid gland, and anastomose with the superior thyreoid artery and with the opposite inferior thyreoid artery.

The **transverse scapular artery** (suprascapular artery) passes at first downwards and lateralwards across the Scalenus anterior and phrenic nerve, under cover of the Sternocleidomastoideus; it then crosses the subclavian artery and the brachial plexus, and runs behind and parallel with the clavicle and Subclavius, and beneath the inferior belly of the Omohyoideus, to the superior border of the scapula; it passes over the superior transverse ligament of the scapula, which separates it from the suprascapular nerve, and enters the supraspinatous fossa (fig. 629). In this situation it lies close to the bone, and supplies branches to the Supraspinatus. It then descends behind the neck of the scapula, through the great scapular notch and beneath the inferior transverse ligament, to reach the infraspinatous fossa, where, under cover of the Infraspinatus, it anastomoses with the scapular circumflex artery and the descending branch of the transverse cervical artery. Besides distributing branches to the Sternocleidomastoideus, Subclavius, and neighbouring muscles, it gives off a *suprasternal branch*, which crosses over the sternal end of the clavicle to the skin of the upper part of the chest; and an *acromial branch*, which pierces the Trapezius and supplies the skin over the acromion, anastomosing with the thoraco-acromial artery. As the transverse

scapular artery passes over the superior transverse ligament of the scapula, it sends a branch into the subscapular fossa, where it ramifies beneath the Subscapularis, and anastomoses with the subscapular artery and with the descending branch of the transverse cervical artery. The transverse scapular artery also sends articular branches to the acromioclavicular and shoulder-joints, and nutrient arteries to the clavicle and scapula.

The **transverse cervical artery** (a. transversa colli) lies at a higher level than the transverse scapular; it passes behind the Omohyoideus and runs transversely above the posterior belly of that muscle, to the anterior margin of the Levator scapulæ, where it divides into an ascending and a descending branch. It crosses in front of the phrenic nerve and the Scalenii, and in front of or between the divisions of the brachial plexus, and is covered by the Platysma and Sternocleidomastoideus.

The **ascending branch** (superficial cervical artery) ascends beneath the anterior part of the Trapezius, distributing branches to it and to the neighbouring muscles and lymph-glands in the neck, and anastomosing with the superficial branch of the descending ramus of the occipital artery.

The **descending branch** (posterior scapular artery) (fig. 629) passes beneath the Levator scapulæ to the medial angle of the scapula, and then descends under cover of the Rhomboidei along the vertebral border of the scapula as far as the inferior angle. It supplies the Rhomboidei, Latissimus dorsi and Trapezius, and anastomoses with the transverse scapular and subscapular arteries, and with the posterior branches of some of the intercostal arteries.

Peculiarities.—In a large proportion of cases the ascending branch (superficial cervical artery) arises directly from the thyrocervical trunk, and the descending branch (posterior scapular artery) from the third, more rarely from the second, part of the subclavian.

4. The **costocervical artery** (superior intercostal artery) (fig. 621) arises from the posterior aspect of the second part of the subclavian artery on the right side, but from the first part of the artery on the left side. It passes backwards above the cupola of the pleura to the neck of the first rib, and divides into the *arteria intercostalis suprema* and the *arteria cervicalis profunda*.

The **arteria intercostalis suprema** descends behind the pleura in front of the necks of the first and second ribs, and anastomoses with the first aortic intercostal artery. As it crosses the neck of the first rib it lies medially to the anterior division of the first thoracic nerve, and laterally to the first thoracic ganglion of the sympathetic trunk. In the first intercostal space, it gives off a branch which is distributed in a manner similar to the distribution of the aortic intercostals. The branch for the second intercostal space usually joins with one from the first aortic intercostal artery; this branch is not constant, but is more commonly found on the right side; when absent, its place is supplied by an intercostal branch from the aorta.

The **arteria cervicalis profunda** arises, in most cases, from the costocervical trunk, and is analogous to the posterior branch of an aortic intercostal artery: occasionally it is a separate branch from the subclavian artery. Passing backwards above the eighth cervical nerve and between the transverse process of the seventh cervical vertebra and the neck of the first rib, it ascends on the back of the neck, between

FIG. 629.—The scapular and circumflex arteries.

the Semispinales capitis and colli, as high as the second cervical vertebra, supplying the adjacent muscles, and anastomosing with the deep division of the descending branch of the occipital artery, and with branches of the vertebral artery. It gives off a spinal twig which enters the vertebral canal through the foramen between the seventh cervical and first thoracic vertebræ.

The **axilla** is a pyramidal space, situated between the upper part of the lateral wall of the chest and the medial side of the arm.

Boundaries.—The *apex*, which is directed upwards towards the root of the neck, corresponds to the interval between the outer border of the first rib, the superior border of the scapula, and the posterior surface of the clavicle; through it the axillary vessels and nerves enter the space from the neck. The *base*, directed downwards, is broad at the chest but narrow and pointed at the arm; it is formed by the skin and a thick layer of fascia, the *axillary fascia*, extending between the lower border of the Pectoralis major in front, and the lower border of the Latissimus dorsi behind. The *anterior wall* is formed by the Pectorales major and minor, the former covering the whole of this wall, the latter only its central part. The space between the upper border of the Pectoralis minor and the clavicle is occupied by the coracoclavicular fascia (costocoracoid membrane). The *posterior wall* is formed by the Subscapularis above, the Teres major and Latissimus dorsi below. On the *medial side* are the first four ribs with their corresponding Intercostales, and the upper part of the Serratus anterior. On the *lateral side*, where the anterior and posterior walls converge, the space is narrow, and bounded by the humerus, the Coracobrachialis, and the Biceps brachii.

Contents.—It contains the axillary vessels, and the infraclavicular part of the brachial plexus of nerves, with their branches, some branches of the intercostal nerves, and a large number of lymph-glands, together with a quantity of fat and loose areolar tissue. The axillary vessels and the brachial plexus of nerves run from the apex to the base along the lateral wall of the axilla; they are placed nearer to the anterior than to the posterior wall, the axillary vein lying to the thoracic side of the axillary artery and partially concealing it. The thoracic branches of the axillary artery are in contact with the Pectorales, and along the lower margin of the Pectoralis minor the lateral thoracic artery passes to the side of the thorax. The subscapular vessels and nerves descend on the posterior wall in contact with the lower margin of the Subscapularis; the scapular circumflex vessels wind round the lateral border of this muscle, and the posterior humeral circumflex vessels and the axillary nerve curve backwards close to the neck of the humerus. No vessel of any importance exists along the medial or thoracic side, the upper part of the space being crossed merely by a few small branches from the highest thoracic artery. The long thoracic nerve descends on the surface of the Serratus anterior, to which it is distributed; and the intercostobrachial nerve perforates the upper and anterior part of this wall, and passes across the axilla to the medial side of the arm.

The position and arrangement of the lymph-glands are described on pp. 719, 720.

Applied Anatomy.—The axilla is a space of considerable surgical importance. Its vessels and nerves may be the seat of injury or disease: its lymph-glands may require removal; its loose connective and adipose tissue may be readily infiltrated with blood or inflammatory exudation; and the space may be the seat of rapidly growing tumours. Moreover, its base is covered by thin skin, which is well supplied with sebaceous and sweat glands, and is frequently the seat of small abscesses and boils.

Penetrating wounds in the axilla are sometimes accompanied by extensive hæmorrhage, either from wound of the main vessels, or of one of the large branches of the axillary artery, e.g. the lateral thoracic or the subscapular. Where the blood cannot find an easy exit it collects in the space and forms a large swelling which projects in the floor of the axilla and also bulges forwards the Pectoralis major. The treatment consists in freely opening up the cavity, searching for and securing the bleeding vessel.

When suppuration occurs in the axilla, the arrangement of the fasciæ plays a very important part in the direction which the pus takes. As described on p. 488, the coraco-

clavicular fascia, after covering the space between the clavicle and the upper border of the Pectoralis minor, splits to enclose this muscle, and at its lower border is incorporated with the axillary fascia at the anterior fold of the axilla. Suppuration may take place either superficial to or beneath this layer of fascia; that is, either between the Pectorales or behind the Pectoralis minor: in the former case, the abscess would point either at the border of the anterior axillary fold, or in the groove between the Deltoides and the Pectoralis major; in the latter, the pus would have a tendency to surround the vessels and nerves, and ascend into the neck, that being the direction in which there is least resistance. Its progress towards the surface is prevented by the axillary fascia; its progress backwards, by the insertion of the Serratus anterior; forwards, by the coracoclavicular fascia; medialwards, by the wall of the thorax; and lateralwards, by the upper limb. The pus in these cases, after extending into the neck, has been known to spread through the superior opening of the thorax into the mediastinal cavity. Instances have been recorded where the pus found its way along the vessels into the arm.

When opening an axillary abscess, the knife should be entered in the floor of the axilla, midway between the anterior and posterior margins and near the thoracic side of the space. After an incision has been made through the skin and fascia, it is well to use a director and dressing forceps in the manner directed by Hilton.

The relations of the vessels and nerves in the several parts of the axilla are important, for it is the almost universal plan to remove the lymph-glands from the axilla in operating for cancer of the breast. In performing such an operation, it is necessary to proceed with much caution in the direction of the lateral wall and apex of the space, as here the axillary vessels are in danger of being wounded. The subscapular, scapular circumflex, and posterior humeral circumflex vessels on the posterior wall and the thoracic branches along the anterior wall must be avoided. In clearing out the axilla, the axillary vein should first be defined and traced up to the apex of the space by means of a director. In order to do this the sternocostal portion of the Pectoralis major, together with the whole of the Pectoralis minor, must be divided and turned aside, by which means the surgeon is enabled to clear out the axillary cavity more thoroughly. When the apex of the space is reached all the fat and the lymph-glands must be carefully removed and the whole axilla cleared by separating the tissues from above downwards from the vessels, and from the medial and posterior walls, so that when the proceeding is completed the axilla is emptied of all its contents except the main vessels and nerves.

✓ AXILLARY ARTERY (fig. 630)

The axillary artery, the continuation of the subclavian, commences at the outer border of the first rib, and ends at the lower border of the tendon of the Teres major muscle, beyond which the artery takes the name of brachial. Its direction varies with the position of the limb: thus the vessel is nearly straight when the arm is directed at right angles with the trunk, concave upwards when the arm is elevated above this, and convex upwards and lateralwards when the arm lies by the side of the trunk. The first part of the artery is deeply situated, but its terminal part is superficial and is covered only by the skin and fasciæ. The Pectoralis minor muscle crosses the vessel and divides it into three portions; the first part is proximal to, the second behind, and the third distal to the muscle.

The first portion of the axillary artery is covered *anteriorly* by the clavicular portion of the Pectoralis major and by the coracoclavicular fascia, and is crossed by the lateral anterior thoracic nerve, and the thoraco-acromial and cephalic veins; *posterior* to it are the first intercostal space and Intercostalis externus, the first and second digitations of the Serratus anterior, the long thoracic and medial anterior thoracic nerves, and the medial cord of the brachial plexus; on its *lateral side* are the lateral and posterior cords of the brachial plexus; on its *medial side* is the axillary vein which overlaps the artery. The artery is enclosed, together with the axillary vein and the brachial plexus, in a fibrous sheath, the *axillary sheath*, continuous above with the deep cervical fascia.

The second portion of the axillary artery is covered, *anteriorly*, by the Pectorales major and minor; *posterior* to it are the posterior cord of the brachial plexus and some areolar tissue which intervene between it and the Subscapularis; on the *medial side* is the axillary vein, separated from the artery by the medial cord of the brachial plexus and the medial anterior thoracic nerve; on the *lateral side* is the lateral cord of the brachial plexus. The cords of the brachial plexus thus surround the artery on three sides, and separate it from direct contact with the vein and adjacent muscles.

The third portion of the axillary artery extends from the lower border of the Pectoralis minor to the lower border of the Teres major. *In front*, it is covered

than to the posterior fold of the axilla. After dissecting through the areolar tissue and fascia, the median nerve and axillary vein are exposed; these are retracted and, the elbow being bent so as to relax the structures, the ligature is applied. This portion of the artery is occasionally crossed by a muscular slip, the *axillary arch* (p. 480), derived from the *Latissimus dorsi*.

The *first portion* of the axillary artery may be tied in cases of aneurysm encroaching so far upwards that a ligature cannot be applied to the lower part of the artery. Its performance is attended with much difficulty and danger. The student will remark that, in this situation, it would be necessary to divide a thick muscle, and, after incising the coracoclavicular fascia, the artery would be exposed at the bottom of a more or less deep space, with the cephalic and axillary veins in such relation with it as must render the application of a ligature to it particularly hazardous. Under such circumstances, it is an easier and, at the same time, a more advisable operation, to tie the third part of the subclavian artery. The first part of the axillary artery can be best secured by a curved incision with the convexity downwards from a point 1.25 cm. lateral to the sternoclavicular joint to a point 1.25 cm. on the medial side of the coracoid process. The limb is to be well abducted and the head inclined to the opposite side, and the incision carried through the superficial structures, care being taken of the cephalic vein at the lateral end of the incision. The clavicular origin of the *Pectoralis major* is then divided in the whole extent of the wound. The arm is now brought to the side, and the upper edge of the *Pectoralis minor* defined and drawn downwards. The coracoclavicular fascia is divided, and the axillary sheath exposed; this is to be opened with especial care on account of the vein overlapping the artery. The needle should be passed from below, so as to avoid wounding the vein.

Collateral Circulation.—If the axillary artery be tied above the origin of the thoraco-acromial artery, the collateral circulation will be carried on by the same branches as after the ligature of the third part of the subclavian (p. 606); if at a lower point, between the thoraco-acromial and the subscapular arteries, the latter vessel, by its free anastomoses with the transverse scapular and transverse cervical arteries, will become the chief agent in carrying on the circulation; the lateral thoracic artery, if it be below the ligature, will materially contribute by its anastomoses with the intercostal and internal mammary arteries. If the ligature be applied below the origin of the subscapular artery, it will most probably also be below the origins of the two humeral circumflex arteries: the chief agents in restoring the circulation will then be the subscapular and the two humeral circumflex arteries anastomosing with the *arteria profunda brachii*.

The branches of the axillary artery are :

From first part 1. Highest thoracic. From second part { 2. Thoraco-acromial.
3. Lateral thoracic.
From third part { 4. Subscapular.
5. Anterior humeral circumflex.
6. Posterior humeral circumflex.

1. The **highest thoracic artery** (superior thoracic artery) is a small vessel, which arises from the axillary artery near the lower border of the *Subclavius* muscle, but may take origin from the thoraco-acromial artery. Running forwards and medialwards along the upper border of the *Pectoralis minor*, it passes between it and the *Pectoralis major* to the side of the chest. It supplies branches to these muscles, and to the thoracic wall, and anastomoses with the internal mammary and intercostal arteries.

2. The **thoraco-acromial artery** (thoracic axis) is a short trunk, which arises from the front of the axillary artery, its origin being generally overlapped by the upper edge of the *Pectoralis minor*. Passing forwards at the upper border of this muscle, it pierces the coracoclavicular fascia and divides into four branches—pectoral, acromial, clavicular, and deltoid. The *pectoral branch* descends between the two *Pectorales*, and is distributed to them and to the mamma, anastomosing with the intercostal branches of the internal mammary artery and with the lateral thoracic artery. The *acromial branch* runs lateralwards over the coracoid process and under the *Deltoideus*, to which it gives branches; it then pierces that muscle and ends on the acromion in an arterial network formed by branches from the transverse scapular, thoraco-acromial, and posterior humeral circumflex arteries. The *clavicular branch* runs upwards and medialwards between the clavicular part of the *Pectoralis major* and the coracoclavicular fascia; it gives branches to the sternoclavicular joint, and to the *Subclavius*. The *deltoid (humeral) branch*, often arising with the acromial, crosses over the *Pectoralis minor* and runs with the cephalic vein between the *Pectoralis major* and *Deltoideus*, giving branches to both muscles.

3. The **lateral thoracic artery** (long thoracic artery) follows the lower border of the *Pectoralis minor* to the side of the chest, supplies the *Serratus anterior* and

the Pectorales, and sends branches to the axillary lymph-glands, and to the Subscapularis; it anastomoses with the internal mammary, subscapular, and intercostal arteries, and with the pectoral branch of the thoraco-acromial artery. In the female, the lateral thoracic artery is large, and gives off an *external mammary branch* which turns round the free edge of the Pectoralis major and supplies the mamma.

4. The **subscapular artery**, the largest branch of the axillary artery, arises at the lower border of the Subscapularis, which it follows to the inferior angle of the scapula, where it anastomoses with the lateral thoracic and intercostal arteries and with the descending branch of the transverse cervical artery, and ends in the neighbouring muscles and adjacent part of the chest-wall. In the lower part of its course it is accompanied by the thoraco-dorsal nerve; about 4 cm. from its origin it gives off the *scapular circumflex artery*.

The **scapular circumflex artery** (arteria dorsalis scapulæ) is generally larger than the continuation of the subscapular. It curves round the axillary border of the scapula, traversing the triangular space between the Subscapularis above, the Teres major below, and the long head of the Triceps laterally (fig. 631); it enters the infraspinatus fossa under cover of the Teres minor, and anastomoses with the transverse scapular artery and the descending branch of the transverse cervical artery. It gives off two branches: one (*infrascapular*) enters the subscapular

FIG. 631.—The scapular and circumflex arteries.

fossa beneath the Subscapularis, which it supplies, and anastomoses with the transverse scapular artery and the descending branch of the transverse cervical artery; the other is continued along the axillary border of the scapula, between the Teres major and the Teres minor, and at the dorsal surface of the inferior angle anastomoses with the descending branch of the transverse cervical artery. In addition to these, small branches are distributed to the posterior part of the Deltoideus and the long head of the Triceps brachii, anastomosing with an ascending branch of the arteria profunda brachii.

5. The **anterior humeral circumflex artery** (fig. 631), a small artery, arises from

the lateral side of the axillary artery at the lower border of the Subscapularis. It runs horizontally, beneath the Coracobrachialis and short head of the Biceps brachii, in front of the neck of the humerus. On reaching the intertubercular sulcus, it gives off a branch which ascends in the sulcus to supply the head of the humerus and the shoulder-joint. The trunk of the vessel is then continued onwards beneath the long head of the Biceps brachii and the Deltoideus, and anastomoses with the posterior humeral circumflex artery.

6. The **posterior humeral circumflex artery** (fig. 631), considerably larger than the anterior, arises from the axillary artery at the lower border of the Subscapularis, and runs backwards with the axillary nerve through the quadrangular space bounded by the Subscapularis and Teres minor above, the Teres major below, the long head of the Triceps brachii medially, and the surgical neck of the humerus laterally. It winds round the neck of the humerus and is distributed to the Deltoideus and shoulder-joint, anastomosing with the anterior humeral circumflex artery and arteria profunda brachii.

Peculiarities.—The branches of the axillary artery vary considerably in different subjects. Occasionally the subscapular, humeral circumflex, and profunda arteries arise

from a common trunk, and when this occurs the branches of the brachial plexus surround this trunk instead of the main vessel. Sometimes the axillary artery divides into the radial and ulnar arteries, and occasionally it gives origin to the volar interosseous artery of the forearm.

BRACHIAL ARTERY (fig. 632)

The **brachial artery** commences at the distal margin of the tendon of the *Teres major*, runs straight down the arm, and ends about 1 cm. below the bend of the elbow by dividing into the *radial* and *ulnar arteries*. At first it lies medially to the humerus; but as it descends it gradually inclines to front of the bone, and at the bend of the elbow lies midway between its two epicondyles.

Relations.—The artery is superficial throughout its entire extent, being covered by the skin and the superficial and deep fasciæ; the *lactus fibrosus* (bicipital fascia) lies in front of it opposite the elbow and separates it from the median cubital vein; the median nerve crosses from its lateral to its medial side opposite the insertion of the *Coracobrachialis*. *Posteriorly*, it is separated from the long head of the *Triceps brachii* by the radial nerve and *arteria profunda brachii*. It then lies upon the medial head of the *Triceps brachii*, next upon the insertion of the *Coracobrachialis*, and lastly on the *Brachialis*. *Laterally*, it is in relation above with the median nerve and the *Coracobrachialis*, below with the *Biceps brachii*, the two muscles overlapping the artery to a considerable extent. *Medially*, its upper half is in relation with the medial antibrachial cutaneous and ulnar nerves, its lower half with the median nerve. The basilic vein lies on its medial side, but is separated from it in the lower part of the arm by the deep fascia. The artery is closely accompanied by two *venæ comitantes* which are connected at intervals by short transverse branches.

FIG. 632.—The brachial artery.

THE CUBITAL FOSSA

At the bend of the elbow the brachial artery sinks deeply into a triangular interval, the *cubital fossa*. The base of the triangle is represented by a line connecting the two humeral epicondyles; the sides are formed by the medial edge of the *Brachioradialis* and the lateral margin of the *Pronator teres*; the floor consists of the *Brachialis* and *Supinator*. This fossa contains the terminal part of the brachial artery, its accompanying veins, the radial and ulnar arteries, the median and radial nerves, and the tendon of the *Biceps brachii*. The brachial artery occupies the middle of the fossa, and divides opposite the

neck of the radius into the radial and ulnar arteries; it is covered, *in front*, by the skin, the superficial fascia, and the median cubital vein, the last being separated from the artery by the *lacertus fibrosus*. *Behind* it is the *Brachialis*, which separates it from the elbow-joint. The median nerve lies close to the medial side of the artery above, but is separated from it below by the ulnar head of the *Pronator teres*. The tendon of the *Biceps brachii* is lateral to the artery; the radial nerve rests upon the *Supinator*, and is concealed by the *Brachioradialis*.

Peculiarities.—The brachial artery, accompanied by the median nerve, may leave the medial border of the *Biceps brachii*, and descend towards the medial epicondyle of the humerus; in such cases it usually passes behind the *supracondylar process* of the humerus, from which a fibrous arch is in most cases thrown over the artery; it then runs beneath or through the substance of the *Pronator teres*, to the bend of the elbow. This variation bears considerable analogy with the normal condition of the artery in some of the *canivora*, and has been referred to in the description of the humerus (p. 277 *). Occasionally, the upper part of the artery splits into two trunks which reunite. Frequently it divides at a higher level than usual, and the vessels concerned in this high division are three: viz. radial, ulnar, and interosseous arteries. Most frequently the radial is given off high up, the other limb of the bifurcation consisting of the ulnar and interosseous; in some instances the ulnar originates above the ordinary level, and the radial and interosseous form the other limb of the division; occasionally the interosseous arises high up.

Sometimes long slender vessels, termed *vasa aberrantia*, connect the brachial or the axillary artery with one or other of the arteries of the forearm. These vessels usually join the radial.

The brachial artery is occasionally concealed in some part of its course, by muscular or tendinous slips derived from the *Coracobrachialis*, *Biceps brachii*, *Brachialis*, or *Pronator teres*.

Applied Anatomy.—In spite of the fact that the brachial artery is very superficial and but little protected by surrounding parts, it is seldom wounded. This, no doubt, is due to its situation on the medial side of the arm, which is little exposed to injury.

Compression of the brachial artery is required in cases of amputation and some other operations in the arm and forearm, and may be effected in almost any part of the course of the artery. If pressure be made in the upper part of the arm, it should be directed lateralwards; if in the lower part, backwards, as the artery lies on the medial side of the humerus above, and in front of it below. The most favourable situation is about the middle of the arm, where the artery lies on the tendon of the *Coracobrachialis* on the medial surface of the humerus.

Ligature of the brachial artery may be required in cases of wound of the vessel, and in some cases of wound of the volar arch. It is also sometimes necessary in cases of aneurysm of the brachial, radial, ulnar, or interosseous arteries. The artery may be secured in any part of its course. The chief guides in determining its position are the surface markings produced by the medial margins of the *Coracobrachialis* and *Biceps brachii*, and the known course of the vessel; its pulsation should be carefully felt for before any operation is performed, as the vessel occasionally deviates from its usual position. It is essential in applying a ligature to this vessel that the arm should be held away from the side of the body, and supported only from the elbow, for if the arm be allowed to rest on any firm structure the *Triceps brachii* is pressed forwards and overlaps the vessel, thus making the operation much more difficult.

In the upper third of the arm the brachial artery may be exposed in the following manner. The patient being placed supine, the limb should be raised from the side, and the hand supinated. An incision about 5 cm. in length is made on the medial side of the *Coracobrachialis*, and the subjacent fascia cautiously divided, so as to avoid wounding the medial antibrachial cutaneous nerve or basilic vein, as the latter sometimes runs on the surface of the artery as high as the axilla. The fascia having been divided, it should be remembered that the ulnar nerve and the medial antibrachial cutaneous nerve lie on the medial side of the artery, the median nerve on the lateral side but occasionally superficial to the artery in this situation, and that the *venae comitantes* are also in relation with the vessel, one on either side. These being carefully separated, the aneurysm needle should be passed round the artery from the medial side.

In the case of a high division, the two arteries are usually placed side by side; and if they are exposed in an operation, the surgeon should endeavour to ascertain, by alternately pressing on each vessel, which is connected with the wound or aneurysm; when a ligature may be applied accordingly; if pulsation or hæmorrhage ceases only when both vessels are compressed, both must be tied.

In the middle of the arm the brachial artery may be exposed by making an incision along the medial margin of the *Biceps brachii*. The forearm is then bent so as to relax this muscle which should be drawn aside, and the fascia carefully divided, when the median nerve will be exposed lying upon (sometimes behind) the artery; the nerve being drawn medialwards and the muscle lateralwards, the artery should be separated from its

accompanying veins and secured. In this situation the superior ulnar collateral artery (*inferior profunda artery*) may be mistaken for the main trunk, especially if enlarged from the collateral circulation having become established; this may be avoided by directing the incision towards the *Biceps brachii*, rather than towards the *Triceps brachii*.

The lower part of the brachial artery is of interest on account of the relation it bears to the veins most commonly opened in venesection. Of these vessels, the median cubital vein (median basilic vein) is the largest and most prominent, and consequently the one usually selected for the operation. This vein runs parallel with the brachial artery, from which it is separated by the *lacertus fibrosus* (*bicipital fascia*), and care should be taken, in opening the vein, not to carry the incision so deep as to endanger the artery.

Collateral Circulation.—After the application of a ligature to the brachial artery in the upper third of the arm, the circulation is carried on by branches from the humeral circumflex and subscapular arteries anastomosing with ascending branches from the *arteria profunda brachii*. If the artery be tied below the origins of the *arteria profunda brachii* and superior ulnar collateral artery, the circulation is maintained by the branches of these two arteries anastomosing with the inferior ulnar collateral artery, and with the radial, the ulnar, and the interosseous recurrent arteries.

The branches of the brachial artery are :

1. *Arteria profunda brachii*.
2. Nutrient.
3. Superior ulnar collateral.
4. Inferior ulnar collateral.
5. Muscular.

1. The *arteria profunda brachii* (*superior profunda artery*) is a large vessel which arises from the medial and posterior part of the brachial artery, just distal to the lower border of the *Teres major*. It follows closely the radial nerve, running at first backwards between the medial and lateral heads of the *Triceps brachii*, then along the sulcus for the radial nerve, where it is covered by the lateral head of the *Triceps brachii*, to the lateral side of the arm; there it pierces the lateral intermuscular septum, and, descending between the *Brachioradialis* and the *Brachialis* to the front of the lateral epicondyle of the humerus, ends by anastomosing with the radial recurrent artery. It gives branches to the *Deltoides* and to the muscles between which it lies; it supplies an occasional *nutrient artery* which enters the humerus behind the deltoid tuberosity. A branch ascends between the long and lateral heads of the *Triceps brachii* to anastomose with the posterior humeral circumflex artery; a *middle collateral branch* descends in the medial head of the *Triceps brachii* with the nerve which supplies the *Anconæus* muscle, and assists in forming the anastomosis above the olecranon; and, lastly, a *radial collateral branch* (posterior branch of superior profunda) runs down behind the lateral intermuscular septum to the back of the lateral epicondyle of the humerus, where it anastomoses with the interosseous recurrent and the inferior ulnar collateral arteries.

2. The *nutrient artery* of the humerus arises about the middle of the arm and enters the nutrient canal near the insertion of the *Coracobrachialis*.

3. The *superior ulnar collateral artery* (*inferior profunda artery*), of small size, arises from the brachial a little below the middle of the arm; it frequently springs from the upper part of the *arteria profunda brachii*. It accompanies the ulnar nerve, pierces the medial intermuscular septum, descends between the medial epicondyle and olecranon, and ends under the *Flexor carpi ulnaris* by anastomosing with the posterior ulnar recurrent and inferior ulnar collateral arteries. It sometimes sends a branch in front of the medial epicondyle, to anastomose with the anterior ulnar recurrent artery.

4. The *inferior ulnar collateral artery* (*arteria anastomotica magna*) arises about 5 cm. above the elbow. It passes medialwards upon the *Brachialis* and, piercing the medial intermuscular septum, winds round the back of the humerus between the *Triceps brachii* and the bone, forming, by its junction with the *arteria profunda brachii*, an arch above the olecranon fossa. As the vessel lies on the *Brachialis*, it gives off branches which ascend to join the superior ulnar collateral artery; others descend in front of the medial epicondyle, to anastomose with the anterior ulnar recurrent artery. Behind the medial epicondyle a branch anastomoses with the superior ulnar collateral and posterior ulnar recurrent arteries.

5. The *muscular branches*, three or four in number, are distributed to the *Coracobrachialis*, *Biceps brachii*, and *Brachialis*.

The anastomosis around the elbow-joint (fig. 633).—The vessels engaged in this anastomosis may be conveniently divided into those situated *in front of*, and those

behind the medial and lateral epicondyles of the humerus. The branches anastomosing *in front* of the medial epicondyle are: the anterior branches of the superior and inferior ulnar collateral arteries and the anterior ulnar recurrent artery. Those *behind* the medial epicondyle are: the superior and inferior ulnar collateral arteries and the posterior ulnar recurrent artery. The branches anastomosing *in front* of the lateral epicondyle are: the terminal part of the arteria profunda brachii and the radial recurrent artery. Those *behind* the lateral epicondyle

FIG. 633.—Diagram of the anastomosis around the elbow-joint.

are: the radial collateral branch of the arteria profunda brachii, the inferior ulnar collateral, and interosseous recurrent arteries. There is also an arch of anastomosis above the olecranon, formed by the inferior ulnar collateral artery joining with the interosseous recurrent and the posterior ulnar recurrent arteries (fig. 636).

RADIAL ARTERY (fig. 634)

The radial artery, though smaller than the ulnar, appears, from its direction, to be the continuation of the brachial artery. It begins at the bifurcation of the brachial, about 1 cm. below the bend of the elbow, and passes along the radial side of the forearm to the wrist. It then winds backwards, round the lateral side of the carpus, under cover of the tendons of the Abductor pollicis longus and Extensores pollicis brevis and longus to the upper end of the space between the first and second metacarpal bones where it passes forwards between the two heads of the first Interosseus dorsalis, into the palm of the hand; it crosses towards the ulnar side of the palm, and unites with the deep volar branch of the ulnar artery to form the deep volar arch. The radial artery is therefore divisible into three portions, one in the forearm, a second at the back of the wrist, and a third in the hand.

Relations.—(a) *In the forearm*, the radial artery extends from the neck of the radius to the front part of its styloid process, being placed to the medial side of the body of the bone above, and in front of it below. Its upper part is overlapped by the fleshy belly of the Brachioradialis; the rest of the artery is only covered by the skin, the superficial and deep fasciæ. It lies successively upon the tendon of the Biceps brachii, the Supinator, the Pronator teres, the radial origin of the Flexor digitorum sublimis, the Flexor pollicis longus, the Pronator quadratus, and the lower end of the radius. In the upper third of its course it is placed between the Brachioradialis and the Pronator teres; in the lower two-thirds, between the tendons of the Brachioradialis and Flexor carpi radialis. The superficial branch of the radial nerve is close to the lateral side of the artery in the middle third of its course: and some filaments of the lateral antibrachial cutaneous nerve run along the lower part of the artery as it winds round the wrist. The artery is accompanied by a pair of venæ comitantes.

(b) *At the wrist*, the radial artery reaches the back of the carpus by passing between the radial collateral ligament of the wrist and the tendons of the Abductor pollicis longus and Extensor pollicis brevis. It then descends on the navicular and greater multangular bones, and before disappearing between the heads of the first Interosseus dorsalis is crossed by the tendon of the Extensor pollicis longus. In the interval between the two Extensores pollicis it is crossed by the digital rami of the superficial branch of the radial nerve, which go to the thumb and index finger.

(c) *In the hand*, the radial artery passes from the upper end of the first interosseous space, between the heads of the first Interosseus dorsalis, transversely across the palm; it lies at first beneath the oblique part of the

FIG. 634.—Right radial and ulnar arteries.

Adductor pollicis, then runs between the oblique and transverse parts, or through the transverse part, of that muscle, and, at the base of the fifth metacarpal bone, anastomoses with the deep volar branch from the ulnar artery, completing the *deep volar arch* (fig. 635).

Peculiarities.—In about 12 per cent. of cases the origin of the radial artery is higher than usual; it then arises more often from the axillary or upper part of the brachial than from the lower part of the latter vessel. In the forearm it deviates less frequently from its normal position than the ulnar artery. It sometimes lies on the deep fascia instead of beneath it, and on the surface of the *Brachioradialis* instead of under its medial border; in turning round the wrist, it occasionally lies on, instead of beneath, the *extensor tendons* of the thumb.

Applied Anatomy.—The radial artery is much exposed to injury in its lower third, and is frequently wounded; the injury may be followed by a traumatic aneurysm.

Ligature of the radial artery is required in cases of wounds either of its trunk, or of some of its branches, or for aneurysm. In the middle or distal third of the forearm it is easily reached; but in the proximal third, near the elbow, the operation is attended with some difficulty, owing to the greater depth of the vessel, and its being overlapped by the *Brachioradialis*.

To tie the artery in the proximal third of the forearm, an incision 7 or 8 cm. long should be made through the skin, in a line drawn from the centre of the bend of the elbow to the front of the styloid process of the radius, avoiding the branches of the medial antibrachial vein; when the fascia of the arm is divided, and the *Brachioradialis* drawn aside, the artery will be exposed. The *venæ comitantes* should be separated from the vessel and the ligature passed from the radial to the ulnar side.

In the middle third of the forearm the artery may be exposed by making an incision of similar length on the medial border of the *Brachioradialis*. In this situation, the superficial part of the radial nerve lies in close relation with the lateral side of the artery, and should be avoided.

In the distal third, the artery is easily secured by dividing the skin and fascia between the tendons of the *Brachioradialis* and *Flexor carpi radialis*. When operating on the cadaver, students are apt to forget how near to the surface the artery is in this situation.

The branches of the radial artery may be divided into three groups, corresponding with the three regions in which the vessel is situated.

<i>In the forearm.</i>	<i>At the wrist.</i>	<i>In the hand.</i>
Radial recurrent.	Dorsal carpal.	Princeps pollicis.
Muscular.	First dorsal metacarpal.	Volaris indicis radialis.
Volar carpal.		
Superficial volar.		

The **radial recurrent artery** arises immediately below the elbow. It ascends between the branches of the radial nerve, lying on the *Supinator* and then between the *Brachioradialis* and *Brachialis*; it supplies these muscles and the elbow-joint, and anastomoses with the terminal part of the *arteria profunda brachii*.

The **muscular branches** are distributed to the muscles on the radial side of the forearm.

The **volar carpal branch** is a small vessel which arises near the lower border of the *Pronator quadratus*, and, running across the front of the carpus, anastomoses with the volar carpal branch of the ulnar artery. This anastomosis is joined by a branch from the volar interosseous artery, and by recurrent branches from the deep volar arch, thus forming a *volar carpal network* which supplies the articulations of the wrist and carpus.

The **superficial volar branch** arises from the radial artery, just where this vessel is about to wind round the lateral side of the wrist. Running forwards, it passes through, occasionally over, the muscles of the ball of the thumb, which it supplies, and sometimes anastomoses with the terminal portion of the ulnar artery completing the superficial volar arch. This vessel varies considerably in size: usually it is very small, and ends in the muscles of the thumb; sometimes it is as large as the continuation of the radial.

The **dorsal carpal branch** is a small vessel which arises beneath the *Extensor tendons* of the thumb; crossing the back of the carpus transversely towards the medial border of the hand, it anastomoses with the dorsal carpal branch of the ulnar artery, and with the volar and dorsal interosseous arteries to form a *dorsal*

carpal network. From this network are given off three slender *dorsal metacarpal arteries*, which descend on the second, third, and fourth Interossei dorsales and bifurcate into dorsal digital branches for the supply of the adjacent sides of the middle, ring, and little fingers respectively; they communicate with the proper volar digital branches of the superficial volar arch; near their origins they anastomose with the deep volar arch by the *superior perforating arteries*, and near their points of bifurcation with the common volar digital vessels of the superficial volar arch by the *inferior perforating arteries*.

The **first dorsal metacarpal artery** arises just before the radial artery passes between the two heads of the first Interosseus dorsalis, and divides almost immediately into two branches which supply the adjacent sides of the thumb and index finger; the radial side of the thumb receives a branch directly from the radial artery.

The **arteria princeps pollicis** arises from the radial artery just as it turns medially towards the deep part of the hand; it descends between the first Interosseus dorsalis and the oblique part of the Adductor pollicis, along the medial side of the metacarpal bone of the thumb to the base of the first phalanx, where it lies beneath the tendon of the Flexor pollicis longus and divides into two branches. These make their appearance between the medial and lateral insertions of the oblique part of the Adductor pollicis, and run along the sides of the thumb, forming on the volar surface of the last phalanx an arch, from which branches are distributed to the integument and subcutaneous tissue of the thumb.

The **arteria volaris indicis radialis**, frequently a branch of the proximal part of the arteria princeps pollicis, descends between the first Interosseus dorsalis and the transverse part of the Adductor pollicis, and runs along the lateral side of the index finger to its extremity, where it anastomoses with the proper digital artery supplying the medial side of the finger. At the lower border of the transverse part of the Adductor pollicis this vessel anastomoses with the arteria princeps pollicis, and gives a communicating branch to the superficial volar arch.

The arteria princeps pollicis and arteria volaris indicis radialis may spring from a common trunk termed the *first volar metacarpal artery*.

The **deep volar arch** (deep palmar arch) (fig. 635) is formed by the anastomosis of the terminal part of the radial artery with the deep volar branch of the ulnar artery. It lies upon the proximal ends of the metacarpal bones and on the Interossei, and is covered by the oblique part of the Adductor pollicis, the flexor tendons of the fingers, and the Lumbricales. Alongside it, but running in the opposite direction—that is to say, towards the lateral side of the hand—is the deep branch of the ulnar nerve.

The branches of the deep volar arch are: volar, metacarpal, perforating, and recurrent.

Volar metacarpal arteries, three in number, arise from the convexity of the deep volar arch; they run distally upon the Interossei of the second, third, and fourth spaces, and anastomose at the clefts of the fingers with the common digital branches of the superficial volar arch.

Perforating branches, three in number, pass backwards from the deep volar arch, through the second, third, and fourth interosseous spaces and between the heads of the corresponding Interossei dorsales, to anastomose with the dorsal metacarpal arteries.

Recurrent branches arise from the concavity of the deep volar arch; they ascend in front of the wrist, supply the intercarpal articulations and end in the volar carpal network.

ULNAR ARTERY (fig. 635)

The **ulnar artery**, the larger of the two terminal branches of the brachial artery, begins about 1 cm. below the bend of the elbow, and, passing obliquely downwards, reaches the ulnar side of the forearm at a point about midway between the elbow and the wrist. It then runs along the ulnar border to the wrist, crosses the transverse carpal ligament on the radial side of the pisiform bone and immediately beyond this bone divides into two branches, which enter into the formation of the superficial and deep volar arches.

Relations.—(a) *In the forearm.*—The *upper half* of the vessel is deeply seated, being covered by the Pronator teres, Flexor carpi radialis, Palmaris longus, and Flexor digitorum sublimis; it lies upon the Brachialis and Flexor digitorum

profundus. The median nerve is in relation with the medial side of the artery for about 2.5 cm. and then crosses the it by the ulnar head of the Pronator teres. The *lower half* lies upon the

FIG. 635.—Right radial and ulnar arteries.
Deep view.

Flexor digitorum profundus; it is covered by the skin, superficial and deep fasciæ, and is placed between the Flexor carpi ulnaris and Flexor digitorum sublimis.

It is accompanied by two venæ comitantes, and is overlapped in its middle third by the Flexor carpi ulnaris; the ulnar nerve lies on the medial side of the lower two-thirds of the artery, and the palmar cutaneous branch of the nerve descends on the lower part of the vessel to the palm of the hand.

(b) *At the wrist* (fig. 634) the ulnar artery is covered by the integument and the volar carpal ligament, and lies upon the transverse carpal ligament. On its medial side is the pisiform bone, and, somewhat behind the artery, the ulnar nerve.

Peculiarities.—The ulnar artery varies in its origin in about 8 per cent. of cases; it frequently arises above the elbow, the brachial being more often the source of origin than the axillary. When its origin is normal, the course of the vessel is rarely changed. When it arises high up, it is almost invariably superficial to the flexor muscles in the forearm, lying commonly beneath the fascia, more rarely between the fascia and skin; the brachial artery then gives off the common interosseous artery, and the latter, the anterior and posterior ulnar recurrent arteries. Occasionally it is subcutaneous in the upper part of the forearm, and subaponeurotic in the lower part.

Applied Anatomy.—Ligature of the ulnar artery is required in cases of wound of the artery, or

of its branches, or in consequence of aneurysm. Ligature of the artery in the upper half of the forearm is attended with some difficulty as this part of the vessel is deeply seated beneath the superficial flexor muscles. An incision is to be made in the course of a line drawn from the front of the medial epicondyle of the humerus to the lateral side of the pisiform bone, so that the centre of the incision is three fingers' breadths below the medial epicondyle. The skin and superficial fascia having been divided, and the deep fascia exposed, the white line which separates the Flexor carpi ulnaris from the other flexor muscles is to be sought for, and the fascia incised in this line. The Flexor carpi ulnaris is now to be carefully separated from the other muscles, when the ulnar nerve will be exposed lying on the Flexor digitorum profundus, and must be drawn aside. The artery, accompanied by its venæ comitantes, lies to the lateral side of the nerve. In the middle

and lower thirds of the forearm, the artery may be easily secured by making an incision on the radial side of the tendon of the Flexor carpi ulnaris: when the deep fascia is divided, and the tendon separated from the Flexor digitorum sublimis, the vessel will be exposed, accompanied by its venæ comitantes, the ulnar nerve lying on its medial side.

The branches of the ulnar artery may be arranged in the following groups:

<i>In the forearm</i>	Anterior recurrent.	<i>At the wrist</i>	Volar carpal.
	Posterior recurrent.		Dorsal carpal.
	Common interosseous.	<i>In the hand</i>	Deep volar.
	Muscular.		Superficial volar arch.

The **anterior ulnar recurrent artery** arises immediately below the elbow-joint, runs upwards between the Brachialis and Pronator teres, supplies twigs to those muscles, and, in front of the medial epicondyle, anastomoses with the superior and inferior ulnar collateral arteries.

The **posterior ulnar recurrent artery** is much larger, and arises somewhat lower than the preceding artery. It passes backwards and medialwards on the Flexor digitorum profundus, behind the Flexor digitorum sublimis, and ascends behind the medial epicondyle of the humerus. In the interval between this process and the olecranon, it lies beneath the Flexor carpi ulnaris, and ascends between the heads of this muscle, in relation with the ulnar nerve; it supplies the neighbouring muscles and the elbow-joint, and anastomoses with the superior and inferior ulnar collateral and the interosseous recurrent arteries (fig. 636).

The **common interosseous artery** (fig. 635), about 1 cm. in length, arises immediately below the tuberosity of the radius, and, passing backwards to the upper border of the antibrachial interosseous membrane, divides into two branches, the *volar* and *dorsal interosseous arteries*.

The **volar interosseous artery** (fig. 635) descends on the volar surface of the antibrachial interosseous membrane, accompanied by the volar interosseous branch of the median nerve, and overlapped by the contiguous margins of the Flexor digitorum profundus and Flexor pollicis longus; it gives off *muscular* branches, and the *nutrient* arteries of the radius and ulna. At the upper border of the Pronator quadratus it pierces the membrane and reaches the back of the forearm, where it anastomoses with the dorsal interosseous artery and descends on the back of the wrist in the compartment of the dorsal carpal ligament containing the tendons of the Extensor digitorum communis and Extensor indicis proprius, and joins the dorsal carpal network. The volar interosseous artery gives off a slender branch, the *arteria mediana*, which accompanies the median nerve, and sends offsets to its substance; this artery is sometimes much enlarged, and runs with the median nerve into the palm of the hand. Before the volar interosseous artery pierces the antibrachial interosseous membrane, it sends a branch downwards behind the Pronator quadratus to join the volar carpal network.

The **dorsal interosseous artery** (fig. 636), usually smaller than the volar interosseous artery, passes backwards between the oblique cord and the upper border of the antibrachial interosseous membrane. It appears on the back of the forearm between the contiguous borders of the Supinator and the Abductor pollicis longus, and descends between the superficial and deep layers of muscles, to both of which it distributes branches. As it lies upon the Abductor pollicis longus and the Extensor pollicis brevis, it is accompanied by the deep branch of the radial nerve. At the lower part of the forearm it anastomoses with the termination of the volar interosseous artery, and with the dorsal carpal network. It gives off, near its origin, the *interosseous recurrent artery*, which ascends to the interval between the lateral epicondyle and olecranon, on or through the fibres of the Supinator, but beneath the Anconæus, and anastomoses with the radial collateral branch of the arteria profunda brachii, the posterior ulnar recurrent, and the inferior ulnar collateral arteries.

The **muscular branches** are distributed to the muscles along the ulnar side of the forearm.

The **volar carpal branch** is a small vessel which crosses the front of the carpus behind the tendons of the Flexor digitorum profundus; it anastomoses with the volar carpal branch of the radial artery, and assists in forming the volar carpal network.

The **dorsal carpal branch** arises immediately above the pisiform bone, and winds backwards beneath the tendon of the Flexor carpi ulnaris; it passes across

the dorsal surface of the carpus under cover of the extensor tendons, anastomoses with the dorsal carpal branch of the radial artery, and assists in forming the dorsal carpal network. Close to its origin it gives off a small branch, which runs along

FIG. 636.—Arteries of the back of the right forearm and hand.

the ulnar side of the fifth metacarpal bone, and supplies the ulnar side of the dorsal surface of the little finger.

The **deep volar branch** (fig. 635) passes between the Abductor digiti quinti and Flexor digiti quinti brevis and through the origin of the Opponens digiti quinti; it anastomoses with the radial artery, and completes the deep volar arch.

The **superficial volar arch** (superficial palmar arch) (fig. 634) is formed mainly by the ulnar artery, and is usually completed by a branch from the *arteria volaris indicis radialis*, but sometimes by the superficial volar artery or by a branch from the *arteria princeps pollicis* of the radial artery. The arch passes across the palm, describing a curve, with its convexity downwards.

Relations.—It is covered by the skin, the *Palmaris brevis*, and the palmar aponeurosis. It lies upon the transverse carpal ligament, the *Flexor digiti quinti brevis* and *Opponens digiti quinti*, the tendons of the *Flexor digitorum sublimis*, the *Lumbricales*, and the divisions of the median and ulnar nerves.

Three **common volar digital arteries** (fig. 634) arise from the convexity of the superficial volar arch and proceed downwards on the second, third, and fourth *Lumbricales*. Each is joined by the corresponding volar metacarpal artery, and then divides into a pair of *proper volar digital arteries* which run along the contiguous sides of the index, middle, ring, and little fingers, behind the corresponding digital nerves; they anastomose freely in the subcutaneous tissue of the finger tips and by smaller branches near the interphalangeal joints. Each gives off a couple of dorsal branches which anastomose with the dorsal digital arteries, and supply the soft parts on the back of the second and third phalanges, including the matrix of the finger-nail. The proper volar digital artery for the medial side of the little finger springs from the ulnar artery under cover of the *Palmaris brevis*.

Applied Anatomy.—Wounds of the volar arches are always difficult to deal with. When the superficial arch is involved it is generally possible (enlarging the wound when necessary) to secure the vessel and tie it on both sides of the bleeding point; or in cases where it is found impossible to encircle the vessel with a ligature, a pair of Wells's artery clips may be applied and left on for twenty-four or forty-eight hours. Failing this, the wound may be plugged with gauze and an outside dressing carefully bandaged on. The plug should be allowed to remain untouched for three or four days. It is useless in these cases to ligature one of the arteries of the forearm alone, and indeed simultaneous ligature of both radial and ulnar arteries above the wrist is often unsuccessful, on account of the anastomosis carried on by the carpal arches. Therefore, upon the failure of pressure to arrest hæmorrhage, it is expedient to apply a ligature to the brachial artery.

When an incision for deep-seated suppuration in the tendon-sheath is required, the situation of the superficial arch must always be borne in mind, and the incisions placed either above or below it. The position of the common digital branches of the artery must also be remembered, and the incisions made in front of the heads of the metacarpal bones and not between them.

ARTERIES OF THE TRUNK

DESCENDING AORTA

The **descending aorta** is divided into two portions, the *thoracic* and *abdominal*, in correspondence with the two great cavities in which it is situated.

THORACIC AORTA (fig. 637)

The **thoracic aorta** is contained in the posterior mediastinal cavity. It begins at the lower border of the fourth thoracic vertebra where it is continuous with the aortic arch, and ends in front of the lower border of the twelfth thoracic vertebra at the aortic hiatus in the Diaphragm. At its commencement, it is situated on the left of the vertebral column; it approaches the median line as it descends, and at its termination lies in front of the column.

Relations.—It is in relation, *anteriorly*, from above downwards, with the root of the left lung, the pericardium, the œsophagus, and the Diaphragm; *posteriorly*, with the vertebral column, the hemiazygos and accessory hemiazygos veins; on the *right side*, with the azygos vein and thoracic duct; on the *left side*, with the left pleura and lung. The œsophagus, with its accompanying plexus of nerves lies on the right side of the aorta above; but at the lower part of the thorax it is placed in front of the aorta, and, close to the Diaphragm, is situated on its left side.

Peculiarities.—The lumen of the aorta is occasionally found to be partly or completely obliterated, either at the aortic isthmus, or close to the point where the ductus arteriosus

opens into it. This condition is known as *coarctation of the aorta*. It may be either congenital or acquired. In the former case the infant usually dies at or soon after birth. In the latter case it is apparently due to an abnormal extension of the peculiar tissue of the ductus into the aortic wall, giving rise to a simultaneous stenosis of both vessels as it contracts after birth. This form of coarctation is compatible with many years of normal life, and leads to the establishment of an extensive collateral circulation to carry blood to

FIG. 637.—The heart and thoracic aorta, viewed from the left side.

the aorta immediately below the stenosis by means of the following vessels—Firstly, the internal mammary, anastomosing with the intercostal arteries, with the inferior phrenic of the abdominal aorta by means of the musculophrenic and pericardiophrenic, and largely with the inferior epigastric. Secondly, the costocervical trunk, anastomosing anteriorly by means of a large branch with the first aortic intercostal, and posteriorly with the posterior branch of the same artery. Thirdly, the inferior thyreoid, by means of a branch about the size of an ordinary radial, forming a communication with the first aortic intercostal. Fourthly, the transverse cervical, by means of very large communications with the posterior branches of the intercostals. Fifthly, the branches (of the subclavian and axillary) going to the side of the chest enlarge, and anastomose freely with the lateral branches of the intercostals. In a second case Wood describes the anastomoses

in a somewhat similar manner, adding the remark, that 'the blood which was brought into the aorta through the anastomoses of the intercostal arteries appeared to be expended principally in supplying the abdomen and pelvis; while the supply to the lower extremities had passed through the internal mammary and epigastrics.'

Applied Anatomy.—The effects likely to be produced by aneurysm of the thoracic aorta, a disease of common occurrence, must now be considered. When the great depth of the vessel from the surface, and the number of important structures which surround it, are remembered, it may easily be conceived what a variety of obscure symptoms are likely to arise from disease of this vessel, and how they may be mistaken for those of other affections. Aneurysm of the thoracic aorta most usually extends backwards, along the left side of the vertebral column, producing absorption of the bodies of the vertebrae, with curvature of the column; while the irritation or pressure on the medulla spinalis will give rise to pain, either in the chest, back, or loins, with radiating pain in the left upper intercostal spaces, from pressure on the intercostal nerves; at the same time the aneurysm may project backwards on either side of the vertebral column, beneath the skin, as a pulsating swelling, simulating abscess connected with diseased bone; or it may displace the œsophagus, or compress the lung on one or the other side. If the aneurysm extend forward, it may press upon and displace the heart, giving rise to palpitation and other symptoms of disease of that organ; it may displace or compress the œsophagus, causing pain and difficulty of swallowing; and ultimately even open into it by ulceration, producing fatal hæmorrhage. If the aneurysm extend to the right side, it may press upon the thoracic duct; or it may burst into the pleural cavity, or into the trachea or lung; and, lastly, it may open into the posterior mediastinal cavity. Pressure on one of the bronchi, usually the left, will cause cough, and in time set up bronchiectasis; pressure on the left pulmonary plexus has been said to give rise to asthmatic attacks. Of late years, the diagnosis of thoracic aneurysm has been much facilitated by the employment of the x-rays, by means of which the outline of the sac may be demonstrated.

BRANCHES OF THE THORACIC AORTA

Visceral	{	Pericardial.	Parietal	{	Mediastinal.
		Bronchial.			Superior phrenic.
		(Esophageal.			Intercostal.
					Subcostal.

The **pericardial branches** consist of a few small vessels which are distributed to the posterior surface of the pericardium.

The **bronchial arteries** vary in number, size, and origin. There is as a rule one *right bronchial artery*, which arises from the first aortic intercostal artery, or from the upper left bronchial artery. The *left bronchial arteries* are usually two in number and arise from the thoracic aorta. The upper left bronchial artery arises opposite the fifth thoracic vertebra, the lower just below the level of the left bronchus. Each vessel runs on the posterior surface of its bronchus, dividing and subdividing along the bronchial tubes, supplying them, the areolar tissue of the lungs, the bronchial lymph-glands, and the œsophagus.

The **œsophageal arteries**, four or five in number, arise from the front of the aorta, and pass obliquely downwards to the œsophagus; on this they form a vascular chain which anastomoses with the œsophageal branches of the inferior thyroid arteries above, and with ascending branches from the left inferior phrenic and left gastric arteries below.

The **mediastinal branches** are numerous small vessels which supply the lymph-glands and loose areolar tissue in the posterior mediastinal cavity.

The **superior phrenic branches** are small, and arise from the lower part of the thoracic aorta; they are distributed to the posterior part of the upper surface of the Diaphragm, and anastomose with the musculophrenic and pericardiophrenic arteries.

Intercostal arteries.—There are usually nine pairs of aortic intercostal arteries. They arise from the back of the aorta, and are distributed to the lower nine intercostal spaces, the first and second spaces being supplied by the *arteria intercostalis suprema*, a branch of the costocervical trunk of the subclavian artery. The *right aortic intercostal arteries* are longer than the left, on account of the position of the aorta on the left side of the vertebral column; they cross the bodies of the vertebrae behind the œsophagus, thoracic duct, and vena azygos, and are covered by the right lung and pleura. The *left aortic intercostal arteries* run backwards on the sides of the vertebrae and are covered by the left lung and pleura; the upper two vessels are crossed by the left superior intercostal vein, the lower vessels by the

hemiazygos and accessory hemiazygos veins. The further course of the intercostal arteries is practically the same on both sides. Opposite the heads of the ribs the sympathetic trunk passes downwards in front of them, and the splanchnic nerves also descend in front of the lower arteries. Each artery then divides into an anterior and a posterior ramus.

The *anterior ramus* crosses the corresponding intercostal space obliquely towards the angle of the upper rib, and thence is continued forward in the costal groove. It is placed at first between the pleura and the posterior intercostal membrane; it then pierces this membrane, and lies between it and the *Intercostalis externus* as far as the angle of the rib; from this onward it runs between the *Intercostales externus* and *internus*, and anastomoses in front with the intercostal branch of the internal mammary or musculophrenic artery. Each artery is accompanied by a vein and a nerve, the former being above and the latter below the artery, except in the upper spaces, where the nerve is at first above the artery. The first aortic intercostal artery anastomoses with the *arteria intercostalis suprema*, and may form the chief supply of the second intercostal space. The lower two intercostal arteries are continued anteriorly from the intercostal spaces into the abdominal wall, and anastomose with the subcostal, superior epigastric, and lumbar arteries.

Each anterior ramus gives off the following branches:

Collateral intercostal.
Muscular.

Lateral cutaneous.
Mammary.

The *collateral intercostal branch* comes off the anterior ramus of the intercostal artery near the angle of the rib, and descends to the upper border of the rib below, along which it courses to anastomose with an intercostal branch of the internal mammary or musculophrenic artery.

Muscular branches are given to the *Intercostales* and *Pectorales*, and to the *Serratus anterior*; they anastomose with the highest and lateral thoracic branches of the axillary artery.

The *lateral cutaneous branches* accompany the lateral cutaneous branches of the thoracic nerves.

Mammary branches are given off by the vessels in the third, fourth, and fifth spaces; they increase considerably in size during the period of lactation.

Each *posterior ramus* runs backwards through a space which is bounded above and below by the necks of the ribs, medially by the body of a vertebra, and laterally by an anterior costotransverse ligament. It gives off a *spinal branch* which enters the vertebral canal through the intervertebral foramen and is distributed to the *medulla spinalis* and its membranes and the *vertebræ*, anastomosing with the spinal arteries above and below and with the artery of the opposite side. It then courses over the transverse process with the posterior division of the thoracic nerve, supplies branches to the muscles of the back, and a cutaneous branch which accompanies the cutaneous branch of the posterior division of the corresponding nerve.

Applied Anatomy.—The position of the anterior rami of the intercostal vessels should be borne in mind in performing the operation of *paracentesis thoracis*. The puncture should never be made nearer the middle line posteriorly than the angle of the rib, as the artery crosses the space medially to this point. In the lateral portion of the chest, where the puncture is usually made, the artery lies at the upper part of the intercostal space, and therefore the puncture should be made just above the upper border of the rib forming the lower boundary of the space.

The *subcostal arteries*, so named because they lie below the last ribs, are in series with the intercostal arteries. Each passes along the lower border of the twelfth rib behind the kidney and in front of the *Quadratus lumborum* muscle, and is accompanied by the twelfth thoracic nerve. It then pierces the posterior aponeurosis of the *Transversus abdominis*, and, passing forward between this muscle and the *Obliquus internus*, anastomoses with the superior epigastric, lower intercostal, and lumbar arteries. Each subcostal artery gives off a posterior branch which has a distribution similar to the posterior ramus of an intercostal artery.

A small *aberrant artery* is sometimes found arising from the right side of the thoracic aorta near the origin of the right bronchial. It passes upwards and to the right behind the trachea and the oesophagus, and may anastomose with the right *arteria intercostalis suprema*. It represents the remains of the right dorsal aorta (p. 121), and in a small proportion of cases is enlarged to form the first part of the right subclavian artery.

ABDOMINAL AORTA (fig. 638)

The abdominal aorta begins at the aortic hiatus of the Diaphragm, in front of the lower border of the body of the last thoracic vertebra, and, descending in front of the vertebral column, ends on the body of the fourth lumbar vertebra, a little to the left of the middle line, by dividing into the two common iliac arteries. It diminishes rapidly in size, in consequence of the large branches which arise from it.

FIG. 638.—The abdominal aorta and its branches.

Relations.—The abdominal aorta is covered, *anteriorly*, by the omental bursa and stomach, behind which are the branches of the coeliac artery and the coeliac plexus of nerves; below these, by the lienal vein, the pancreas, the left renal vein, the inferior part of the duodenum, the root of the mesentery, and aortic plexus of nerves. *Posteriorly*, it is separated from the lumbar vertebrae and intervertebral fibrocartilages by the anterior longitudinal ligament and left lumbar veins. On the *right side* it is in relation above with the cisterna chyli, thoracic duct, azygos vein, and the right crus of the Diaphragm—the last separating it from the upper part of the inferior vena cava, and from the right coeliac ganglion; the inferior vena cava is in contact with the aorta below the level of the second lumbar vertebra.

On the *left side* are the left crus of the Diaphragm, the left celiac ganglion, the ascending part of the duodenum, some coils of the small intestine, the left sympathetic trunk, inferior mesenteric and left testicular vessels, and the left ureter.

Applied Anatomy.—The abdominal aorta may be the seat of an aneurysm either at its upper part, close to and often involving the celiac artery, or at its lower part, near the bifurcation. Occasionally aneurysms are met with on some of the branches of the aorta, e.g., the mesenteric or lienal arteries.

When an aneurysm is connected with the posterior part of the abdominal aorta, it usually produces absorption of the bodies of the vertebræ. Pain is invariably present, and is usually of two kinds—a fixed and constant pain in the back, caused by the tumour pressing on or displacing the branches of the celiac plexus and splanchnic nerves; and a sharp lancinating pain, radiating along those branches of the lumbar nerves which are pressed on by the tumour; hence the pain in the loins, the testes, the hypogastrium, and in the lower limb (generally of the left side). This form of aneurysm usually bursts into or behind the peritoneal cavity.

When an aneurysm is connected with the front of the aorta near the celiac artery, it forms a pulsating tumour in the left hypochondriac or epigastric regions, usually attended with symptoms of disturbance of the digestive tube, as sickness, dyspepsia, or constipation, and accompanied by pain, which is constant, but nearly always fixed, in the loins, epigastrium, or some part of the abdomen; the radiating pain being rare, as the lumbar nerves are seldom implicated. This form of aneurysm may burst into the peritoneal cavity, behind the peritoneum, between the layers of the mesentery, or, more rarely, into the duodenum; it rarely extends backwards so as to affect the vertebral column.

Occlusion of the abdominal aorta by thrombosis or embolism is rare, but produces very severe symptoms when it does occur. The patient complains of intense pain in the legs; pallor of the legs, followed by coldness, lividity, paresis, paralysis, and finally gangrene are likely to succeed, death usually supervening within a fortnight.

The abdominal aorta has been tied in several cases, and although none of the patients permanently recovered, still, as one case lived forty-eight days, the possibility of the re-establishment of the circulation may be considered to be proved.

Collateral Circulation.—The collateral circulation would be carried on by the anastomoses between the internal mammary and the inferior epigastric arteries; by the free communication between the superior and inferior mesenteric arteries, if the ligature were placed between these vessels; or by the anastomosis between the inferior mesenteric and the internal pudendal arteries, when (as is more common) the point of ligature is below the origin of the inferior mesenteric artery; and possibly by the anastomoses of the lumbar arteries with the branches of the hypogastric artery.

BRANCHES OF THE ABDOMINAL AORTA

The branches of the abdominal aorta may be divided into three sets: visceral, parietal, and terminal.

Visceral branches.

Celiac.
Superior mesenteric.
Inferior mesenteric.
Middle suprarenal.
Renal.
• Testicular (in the male).
• Ovarian (in the female).

Parietal branches.

Inferior phrenic.
Lumbar.
Middle sacral.

Terminal branches.

Common iliac.

Of the visceral branches, the celiac artery and the superior and inferior mesenteric arteries are unpaired; the suprarenal, renal, testicular, and ovarian arteries are paired. Of the parietal branches, the middle sacral artery is unpaired; the inferior phrenic and lumbar arteries are paired. The terminal branches are paired.

CELIAC ARTERY (figs. 639, 640)

The celiac artery is a thick trunk, about 1.25 cm. long, which arises from the front of the aorta, just below the aortic hiatus of the Diaphragm, it passes nearly horizontally forwards, and divides into three large branches, (1) *left gastric*, (2) *hepatic*, and (3) *lienal* or *splenic*; it occasionally gives off one of the inferior phrenic arteries.

Relations.—The celiac artery is covered by the omental bursa and surrounded by the celiac plexus of nerves. On its *right side* are the right celiac

ganglion and the caudate process of the liver, on its *left side* the left cœliac ganglion and the cardiac end of the stomach. *Below* it are the upper border of the pancreas and the lienal vein.

1. The **left gastric artery** (coronary artery), the smallest branch of the cœliac artery, passes upwards and to the left, behind the omental bursa, to the cardiac orifice of the stomach. Here it gives off branches which ascend on the œsophagus, and anastomose with the aortic œsophageal arteries; others supply the cardiac part of the stomach, and anastomose with branches of the lienal artery. The artery then runs from left to right, along the lesser curvature

FIG. 639.—The cœliac artery and its branches; the liver has been raised, and the lesser omentum and anterior layer of the greater omentum removed.

of the stomach to the pylorus, between the layers of the lesser omentum; it gives branches to both surfaces of the stomach and anastomoses with the right gastric artery.

2. The **hepatic artery** is intermediate in size between the left gastric and lienal. It is first directed forwards and to the right, to the upper margin of the superior part of the duodenum, forming the lower boundary of the epiploic foramen (foramen of Winslow). It then crosses the portal vein anteriorly, and ascends between the layers of the lesser omentum, and in front of the epiploic foramen, to the porta hepatis, where it divides into a right and a left branch, which supply the corresponding lobes of the liver, accompanying the ramifications of the portal vein and hepatic ducts. The hepatic artery, in its course along the right border of the lesser omentum, is in relation with the common bile-duct and portal vein, the duct lying to the right of the artery, and the vein behind. The distribution of the hepatic artery is described with the anatomy of the liver, in the section on Splanchnology.

Its branches are :

Right gastric.

Gastroduodenal { Right gastro-epiploic.
Superior pancreaticoduodenal.

Cystic.

The **right gastric artery** (pyloric artery) arises from the hepatic, above the pylorus, descends to the pyloric end of the stomach, and passes from right to left along its lesser curvature, supplying it with branches, and anastomosing with the left gastric artery.

The **gastroduodenal artery** (fig. 640) is a short but large branch, which descends, near the pylorus, between the superior part of the duodenum and the neck of the

FIG. 640.—The coeliac artery and its branches; the stomach has been raised and the peritoneum removed.

Branches to greater omentum

pancreas, and divides at the lower border of the duodenum into two branches, the *right gastro-epiploic* and the *superior pancreaticoduodenal* arteries. Previous to its division it gives off two or three small branches to the pyloric end of the stomach and to the pancreas.

The **right gastro-epiploic artery** runs from right to left along the greater curvature of the stomach, between the layers of the greater omentum, anastomosing with the left gastro-epiploic branch of the lienal artery. Except at the pylorus, where it is in contact with the stomach, it lies about a finger's breadth from the greater curvature. This vessel gives off numerous branches, some of which ascend to supply both surfaces of the stomach, while others descend in the greater omentum and anastomose with branches of the middle colic artery.

The **superior pancreaticoduodenal artery** descends between the duodenum and the head of the pancreas. It supplies both these organs, and anastomoses with the inferior pancreaticoduodenal branch of the superior mesenteric artery, and with the pancreatic branches of the lienal artery.

The **cystic artery** (fig. 639), usually a branch of the right hepatic artery, passes downwards and forwards along the neck of the gall-bladder, and divides into two branches, one of which ramifies on the free surface, the other on the attached surface of the gall-bladder.

3. The **lienal or splenic artery**, the largest branch of the coeliac artery, is remarkable for the tortuosity of its course. Accompanied by the lienal vein which lies below it, it passes horizontally to the left, behind the stomach and the omental bursa of the peritoneum, and along the upper border of the pancreas; it then crosses in front of the upper part of the left kidney, and, on arriving near the spleen, divides into branches; some of these enter the hilum of the spleen between the two layers of the phrenicocolical ligament; some are given to the pancreas, while others pass to the greater curvature of the stomach between the layers of the gastrosplenic ligament. Its branches are:

Pancreatic.

Short gastric.

Left gastro-epiploic.

The **pancreatic branches** are numerous small vessels supplying the body and tail of the pancreas; they are derived from the lienal artery as it runs behind the upper border of the pancreas. One branch, larger than the rest, is sometimes given off near the tail of the pancreas; it runs from left to right near the posterior surface of the gland, following the course of the pancreatic duct, and is called the *arteria pancreatica magna*. These vessels anastomose with the pancreatic branches of the superior and inferior pancreaticoduodenal arteries.

The **short gastric arteries** (*vasa brevia*) consist of from five to seven small branches which arise from the end of the lienal artery, and from its terminal divisions. They pass from left to right, between the layers of the gastrosplenic ligament, and are distributed to the greater curvature of the stomach, anastomosing with branches of the left gastric and left gastro-epiploic arteries.

The **left gastro-epiploic artery**, the largest branch of the lienal, runs from left to right about a finger's breadth or more from the greater curvature of the stomach, between the layers of the greater omentum, and anastomoses with the right gastro-epiploic artery. It distributes several ascending branches to both surfaces of the stomach; others descend to supply the greater omentum and anastomose with branches of the middle colic artery.

Applied Anatomy.—Embolism of branches of the lienal artery is tolerably common in heart disease, the embolus coming from the left side of the heart. It is characterised by the occurrence of a sudden sharp pain or 'stitch' in the splenic region, with subsequent local enlargement of the spleen from the formation of an infarct in its substance.

SUPERIOR MESENTERIC ARTERY (fig. 641)

The **superior mesenteric artery** supplies the whole of the small intestine except the superior part of the duodenum; it also supplies the cæcum and the ascending colon and about one-half of the transverse colon. It arises from the front of the aorta about 1.25 cm. below the coeliac artery, and is crossed at its origin by the lienal vein and the neck of the pancreas. It passes downwards and forwards, anterior to the processus uncinatus of the head of the pancreas and the inferior part of the duodenum, and descends between the layers of the mesentery to the right iliac fossa, where, considerably diminished in size, it anastomoses with one of its own branches, viz. the ileocolic artery. In its course it crosses in front of the inferior vena cava, the right ureter, and Psoas major, and forms an arch, the convexity of which is directed forwards and downwards, to the left side. It is accompanied by the superior mesenteric vein, which lies to its right side, and is surrounded by the superior mesenteric plexus of nerves. Its branches are:

Inferior pancreaticoduodenal.
Jejunal and ileal.

Ileocolic.
Right colic.

Middle colic.

The **inferior pancreaticoduodenal artery** springs from the superior mesenteric artery or from its first jejunal branch, opposite the upper border of the inferior part of the duodenum. It courses to the right between the head of the pancreas and duodenum, and then ascends to anastomose with the superior pancreaticoduodenal artery. It distributes branches to the head of the pancreas and to the descending and inferior parts of the duodenum.

The **jejunal and ileal arteries** (*vasa intestini tenuis*) arise from the left side of the superior mesenteric artery. They are usually from twelve to fifteen in

FIG. 641.--The superior mesenteric artery and its branches.

number, and are distributed to the jejunum and ileum. They run nearly parallel with one another between the layers of the mesentery, each vessel dividing into two branches, which unite with adjacent branches, forming a series of arches, the convexities of which are directed towards the intestine (fig. 642). From this first set of arches branches arise, which unite with similar branches from above and below, and thus a second series of arches is formed; from the lower branches of the artery, a third, a fourth, and even a fifth series of arches may be formed, diminishing in size the nearer they approach the intestine. In the short, upper part of the mesentery only one set of arches exists, but as the depth of the mesentery increases, second, third, fourth, and even fifth groups are developed. From the terminal arches numerous small straight vessels arise which encircle the intestine and are distributed to it. From the jejunal and ileal arteries small branches are given off to the lymph-glands and other structures between the layers of the mesentery.

FIG. 642.—Loop of small intestine showing distribution of intestinal arteries.
(From a preparation by Hamilton Drummond.)

The vessels were injected while the gut was *in situ*; the gut was then removed, and an x-ray photograph taken.

FIG. 643.—Arteries of caecum and vermiform process.

The **ileocolic artery** is the lowest branch arising from the concavity of the superior mesenteric artery. It passes downwards and to the right behind the peritoneum, towards the right iliac fossa, where it divides into a superior and an inferior branch; the superior branch anastomoses with the right colic artery, the inferior with the end of the superior mesenteric artery.

The inferior branch of the ileocolic runs towards the upper border of the ileocolic junction and supplies the following branches (fig. 643): (a) *colic*, which pass upwards on the ascending colon; (b) *anterior and posterior cæcal*, which are distributed to the front and back of the cæcum; (c) an *appendicular artery*, which descends behind the termination of the ileum and enters the mesenteriole of the vermiform process; it runs near the free margin of this mesenteriole and ends in branches which supply the vermiform process; and (d) *ileal*, which runs upwards and to the left on the lower part of the ileum, and anastomose with the termination of the superior mesenteric artery.

The **right colic artery** arises from about the middle of the concavity of the superior mesenteric artery, or from a stem common to it and the ileocolic. It passes to the right behind the peritoneum, and in front of the right testicular (or ovarian) artery and vein, the right ureter, and the Psoas major, towards the middle of the ascending colon; sometimes the vessel lies at a higher level, and crosses the descending part of the duodenum and the lower end of the right kidney. At the colon it divides into a descending branch, which anastomoses with the ileocolic artery, and an ascending branch, which anastomoses with the middle colic artery. These branches form arches, from the convexity of which vessels are distributed to the ascending colon.

The **middle colic artery** arises from the superior mesenteric artery just below the pancreas and, passing downwards and forwards between the layers of the transverse mesocolon, divides into a right and a left branch; the former anastomoses with the right colic artery; the latter with the left colic artery, a branch of the inferior mesenteric artery. The arches thus formed are placed about two fingers' breadth from the transverse colon, to which they distribute branches.

INFERIOR MESENTERIC ARTERY (fig. 644)

The **inferior mesenteric artery** supplies the left half of the transverse colon, the whole of the descending colon, the sigmoid colon, and the greater part of the rectum. It is smaller than the superior mesenteric, and arises from the aorta, about 3 or 4 cm. above its division into the common iliacs, and close to the lower border of the inferior part of the duodenum. It descends behind the peritoneum, lying at first anteriorly to, and then on the left side of, the aorta. It crosses the left common iliac artery on the medial side of the left ureter, and is continued into the lesser pelvis as the *superior hæmorrhoidal artery*, between the two layers of the sigmoid mesocolon, and ends on the upper part of the rectum. Its branches are:

Left colic.

Sigmoid.

Superior hæmorrhoidal.

The **left colic artery** runs to the left behind the peritoneum and in front of the Psoas major, and, after a short but variable course, divides into an ascending and a descending branch; the trunk or the branches of the artery cross the left ureter and left testicular vessels. The ascending branch passes in front of the left kidney and between the two layers of the transverse mesocolon where it ends by anastomosing with the middle colic artery; the descending branch anastomoses with the highest sigmoid artery. From the arches formed by these anastomoses branches are distributed to the descending colon and the left half of the transverse colon.

The **sigmoid arteries** (fig. 645), two or three in number, run obliquely downwards and to the left behind the peritoneum and in front of the Psoas major, ureter, and testicular vessels. Their branches supply the lower part of the descending colon and the sigmoid colon, anastomosing above with the left colic artery, and below with the superior hæmorrhoidal artery.

The **superior hæmorrhoidal artery** (fig. 645), the continuation of the inferior mesenteric artery, descends into the pelvis between the layers of the sigmoid mesocolon, crossing, in its course, the left common iliac vessels. It divides, opposite the third sacral vertebra, into two branches; these descend one on either side of the

rectum, and supply its mucous membrane as far as the anal canal, and the upper part of its muscular coat; about 10 or 12 cm. from the anus the two arteries break up into several small branches. These pierce the muscular coat of the bowel and run downwards, as straight vessels placed at regular intervals from each other, in the wall of the gut between its muscular and mucous coats, to the level of the Sphincter ani internus; here they form a series of loops around the lower end of the rectum, and communicate with the middle hæmorrhoidal branches of the hypogastric artery, and with the inferior hæmorrhoidal branches of the internal pudendal artery.

FIG. 644.—The inferior mesenteric artery and its branches.

Applied Anatomy.—Embolism of the mesenteric arteries produces acute and severe symptoms, of which the chief are abdominal pain and tenderness, nausea and vomiting, diarrhœa or constipation; blood is found in the stools of nearly half the patients. In many cases the symptoms closely resemble those of intestinal obstruction.

MIDDLE SUPRARENAL ARTERIES

The **middle suprarenal arteries** are two small vessels which arise, one from either side of the aorta, opposite the superior mesenteric artery. Each passes lateralwards and slightly upwards, over the crus of the Diaphragm, to the suprarenal gland, where it anastomoses with suprarenal branches of the inferior phrenic and renal arteries.

RENAL ARTERIES (fig. 638)

The renal arteries are two large trunks, which arise from the sides of the aorta, immediately below the superior mesenteric artery. Each is directed across the crus of the Diaphragm, so as to form nearly a right angle with the aorta. The *right* is longer than the left, on account of the position of the aorta; it passes behind the inferior vena cava, the right renal vein, the head of the pancreas, and the descending part of the duodenum. The *left* is a little higher than the right; it lies behind the left renal vein, the body of the pancreas

FIG. 645.—Sigmoid colon and rectum, showing distribution of branches of inferior mesenteric artery, and their anastomoses. (From a preparation by Hamilton Drummond.)

Prepared in same manner as Fig. 642.

and the lienal vein, and is crossed by the inferior mesenteric vein. Before reaching the hilum of the kidney, each artery divides into four or five branches; most of these lie between the renal vein and ureter, the vein being in front, the ureter behind, but one or more branches are usually situated behind the ureter. Each vessel gives off some small *inferior suprarenal branches* to the suprarenal gland, and supplies twigs to the ureter and the surrounding cellular tissue and muscles.

One or two accessory renal arteries are frequently found, more especially on the left side: they usually arise from the aorta, and may come off above or below the main artery, the former being the more common position. Instead of entering the kidney at the hilum, they usually pierce the upper or lower part of the kidney.

TESTICULAR ARTERIES (fig. 638)

The **testicular arteries** are two long slender vessels which arise from the front of the aorta a little below the renal arteries. Each passes obliquely downwards and lateralwards behind the peritoneum, resting on the Psoas major; the right artery lies in front of the inferior vena cava and behind the middle colic and ileocolic arteries and the terminal part of the ileum; the left artery passes behind the left colic and sigmoid arteries, and the iliac part of the descending colon. Each artery crosses obliquely over the ureter and the lower part of the external iliac artery to reach the abdominal inguinal ring, through which, accompanied by the other constituents of the spermatic cord, it enters the inguinal canal and passes to the scrotum, where it becomes tortuous and divides into several branches. Two or three of these accompany the ductus deferens, and supply the epididymis, anastomosing with the artery of the ductus deferens; others pierce the back part of the tunica albuginea, and supply the substance of the testis. The testicular artery supplies one or two small branches to the ureter, and in the inguinal canal gives one or two twigs to the Cremaster muscle.

OVARIAN ARTERIES

The **ovarian arteries** in the female correspond to the testicular arteries in the male. They supply the ovaries, are shorter than the testicular arteries, and end in the pelvic cavity. The origin and course of the first part of each artery are the same as those of the testicular artery, but on arriving at the upper opening of the lesser pelvis the artery passes medialwards between the two layers of the broad ligament of the uterus below the uterine tube. At the level of the ovary it runs backwards in the mesovarium and breaks up into branches which are distributed to the ovary. Small branches are given to the ureter and the uterine tube, and one passes on to the side of the uterus, and unites with the uterine artery. Other offsets are continued on the round ligament of the uterus, through the inguinal canal, to the skin of the labium majus and groin.

At an early period of foetal life, when the testes or ovaries lie by the side of the vertebral column, below the kidneys, the testicular and ovarian arteries are short; but with the descent of the testicles into the scrotum, and of the ovaries into the pelvis, the arteries are gradually lengthened.

INFERIOR PHRENIC ARTERIES (fig. 638)

The **inferior phrenic arteries** are two small vessels which supply the Diaphragm. They present much variety in their origins; they may arise separately from the front of the aorta, immediately above the coeliac artery, or by a common trunk, which may spring either from the aorta or from the coeliac artery; sometimes one artery is derived from the aorta, and the other from one of the renal arteries. They diverge from one another across the crura of the Diaphragm, and then run obliquely upwards and lateralwards upon its under surface. The left phrenic passes behind the oesophagus, and runs forwards on the left side of the oesophageal hiatus. The right phrenic passes behind the inferior vena cava, and along the right side of the foramen which transmits that vein. Near the posterior part of the central tendon of the Diaphragm each vessel divides into a medial and a lateral branch. The medial branch curves forwards, and anastomoses with its fellow of the opposite side, and with the musculophrenic and pericardiophrenic arteries. The lateral branch passes towards the side of the thorax, and anastomoses with the lower intercostal arteries, and with the musculophrenic artery. The lateral branch of the right artery gives off a few twigs to the inferior vena cava; and the left artery sends some branches to the oesophagus. Each vessel gives off *superior branches* to the suprarenal gland of its own side. The liver and the spleen also receive a few twigs from the right and left vessels respectively.

LUMBAR ARTERIES

The **lumbar arteries** are in series with the intercostals. They are usually four in number on either side, and arise from the back of the aorta, opposite the bodies of the upper four lumbar vertebræ. A fifth pair, small in size, is occasionally present: it arises from the middle sacral artery. They run lateralwards and backwards on the bodies of the lumbar vertebræ, behind the sympathetic trunk, to the intervals between the adjacent transverse processes, and are then continued into the abdominal wall. The arteries of the right side pass behind the inferior vena cava, and the upper two on either side run behind the corresponding crus of the Diaphragm. The arteries of both sides pass beneath the tendinous arches which give origin to the Psoas major, and are continued behind this muscle and the lumbar plexus. They then cross the Quadratus lumborum, the upper three arteries running behind, the last usually in front of it. At the lateral border of the Quadratus lumborum they pierce the posterior aponeurosis of the Transversus abdominis, and are carried forwards between this muscle and the Obliquus internus. They anastomose with one another and with the lower intercostal, subcostal, ilio-lumbar, deep iliac circumflex, and inferior epigastric arteries.

Branches. Each lumbar artery gives off a *posterior ramus* which passes backwards between the transverse processes, is distributed to the muscles and skin of the back, and furnishes a *spinal branch* which enters the vertebral canal and supplies its contents, anastomosing with the arteries above and below it, and with the artery of the opposite side. Branches are also given by the lumbar arteries and their posterior rami to the neighbouring muscles.

MIDDLE SACRAL ARTERY (fig. 638)
